Preface

So much has been learned of viral and rickettsial infections during the 6 years since the second edition of this book was published as to make the need for a new edition almost imperative In this short interval, several new groups of viruses have been discovered, and the recognition of their position in relation to a variety of infectious processes has gradually unfolded Several viruses, which were known earlier, have been found to have common properties that were previously unsuspected and to possess common antigenic components which have necessitated their reclassification in definite groups Tissue cultures have emerged as highly valuable and widely useful materials for the investigation of viral agents, and the discovery of the cytopathogenic effects of many viruses has resulted in the development of technics which in several instances make the use of intact animals less rewarding than the employment of in vitro procedures Important changes in several conceptual schemes have appeared because of the acquisition and the integration of new information on a broad base Some unifying concepts have been developed, particularly regarding the mechanism of virus multiplication, which serve to diminish if not to abolish the significance of differences between various categories based largely on distinctions among their host species

All of the contributors to this book have concurred with the view of the editors that, because of the remarkable growth of knowledge bearing on viral and rickettsial infections, an attempt at revision of the second edition would undoubtedly have been inadequate Therefore, they have graciously undertaken the tedious and time-consuming task of preparing an entirely new book

This edition is the result of the efforts of 44 contributors, some 14 more than participated in the preparation of the second edition All of the contributors were selected because of their eminence and experience in this field of investigation and because of their special fitness to describe and discuss authoritatively the knowledge available in a particular sector The editors have not attempted to delineate the material considered or the information covered in the several chapters and have carefully avoided influencing either the views or the conclusions of the authors In spite of the full freedom of the contributors to write as they thought best, it is remarkable how small and infrequent are the areas of disagreement and how minor the issues when occasionally they occur

The present volume contains 46 chapters some 7 more than the second edition Three of the new chapters deal with common features of viruses and the infections they induce These are· "Biochemistry of the Virus-Infected Cell," "Virus-Host Cell Relation" and "Chemotherapy and Virus Infection" Two other new chapters are devoted to groups of viruses that have been discovered since the second edition appeared ECHO viruses and Adenoviruses The earlier chapter on "Viral Encephalitides" has been supplanted by 4 chapters concerning "Arthropod-Borne Animal Viruses" and the infections they induce The previous chapter on poliomyelitis has been expanded to 3 chapters· "Poliomyelitis," "Poliomyelitis Pathogenesis and Histopathology" and "Poliomyelitis Control" One chapter on a recently identified disease, "Hemorrhagic Fever," has been added

Four chapters included in the second edition are not represented separately in this book Hemagglutination by viruses is included in the chapter on "Virus-Host Cell Relation" Diagnosis of viral and rickettsial infections is considered in the several chapters dealing with specific disease entities Epidemic keratoconjunctivitis is discussed in relation to the viruses which most commonly are associated with the syndrome, i.e., Adenoviruses. Rift Valley fever is described in the chapter on

"Miscellaneous Arthropod-Borne Virus Infections of Man."

Because of the very large number of references, some of those that were chiefly of historical interest and were included in the second edition have been deleted from the reference lists Such references are identified by the absence of parentheses about either the author's name or the year of publication.

This book is designed, as were the previous editions, to provide comprehensive information relative to viral and rickettsial infections which meets the needs of graduate students of biology, including those who are preparing for a career in medicine It is hoped that it will also prove useful to physicians, teachers and investigators in the biologic sciences

The National Foundation has, as with previous editions, generously provided support for the preparation and the publication of this volume Because of this continuing aid it will be possible to distribute the book at a price considerably below that which would normally be required

The editors are deeply grateful to all of the contributors for the large effort they expended on and the care and the thought they gave to the preparation of manuscripts, the selection of references and the development of illustrative material. They are grateful also for the generous spirit of wholehearted co-operation that has characterized this collaborative undertaking throughout the lengthy process of its development

Contents

out into the cytoplasm Shortly after the obvious increase in S antigen, appreciable amounts of hemagglutinin become discernible in the cytoplasm The two subunits move toward the cell wall where the hemagglutinin is assembled around the S antigen and lipid is incorporated to make the finished infectious particle (cf. Chap. 4 and Figs 34 to 38).

Since the nucleic acids of phage, tobacco mosaic virus and other viruses as well constitute the unadorned infectious principal, they are of great interest not only to virologists but also to biochemists and geneticists. For example, the former see such nucleic acids as tools for studying the production of proteins, i.e , those specific proteins which eventually form the protective cover for the infectious material, as well as proteins which in some instances have enzymatic activity The latter regard them as among the simplest packages capable of carrying genetic information and hope from elucidation of nucleic acid replication and function in viruses to gain insights applicable to genes in higher organisms Incidentally, the viral nucleic acids behave in some respects like the DNA of pneumococci and other bacteria which cause genetic transformation, but perhaps are more aggressive in that they enslave a totally unrelated host cell and usually work it to death in the course of producing quantities of new virus. The bacterial transforming substances, on the other hand, capture closely related organisms and force them to produce progeny like the original organism which supplied the factor

Mutants appear during viral multiplication and are recognized by a variety of distinguishing characteristics Among phages, such markers which are conveniently used in genetic studies are varying plaque types and differing bacterial host ranges, while among influenza viruses antigenic peculiarities, virulence and physical properties provide means for recognizing individuality When infection is induced by two readily distinguishable mutants, most of the progeny resemble one or the other parent, but some individual progeny possess the markers of each parent The last are called recombinants Perhaps even more interesting is the observation that infection with one mutant in the presence of inactivated particles of another mutant can result in a proportion of infectious progeny with certain markers from the inactivated material. This phenomenon is discussed in a number of later chapters, particularly 3, 4 and 7.

The fact that viruses undergo mutations either in nature or in the laboratory is of practical, as well as theoretical, importance Thus, the 17D strain of yellow fever virus, which provides one of the most useful live attenuated vaccines available to preventive medicine, is quite different in many respects from its parent strain (cf. Chap 15) The modern methods for obtaining clones of viruses, particularly the plaque and terminal dilution technics, have made it possible to proceed rather rapidly and with considerable assurance in the search for highly attenuated, reasonably stable mutants of the polioviruses for use in a live vaccine That mutants can be disadvantageous to man is illustrated by influenza (cf. Chap 31) The pandemic of 1957 was caused by the Asian strain of influenza A virus which was appreciably different antigenically from other known strains Furthermore, the vast majority of the world populations had no previous experience with this particular strain and hence were susceptible

PATHOLOGY

Because virology, from its inception, has been concerned with disease, and because most of the early mammalian virologists were trained pathologists, the lesions which characterize the infections have received much attention. The pathologic picture of each disease is described in detail in the appropriate chapters of this book The student probably will be impressed with the monotonous similarity of the lesions found in a given organ system, even though these are caused by different viral or rickettsial agents Thus, the gross and the microscopic findings in pneumonias caused by influenza or psittacosis viruses, or the rickettsia of Q fever, present more common features than differences The same may be said for the viral encephalitides and for the typhus-spotted fever group of rickettsial diseases This should not be surprising since the pathologist requires bacteriologic aid to differentiate most of the bacterial pneumonias from one another. It is of some consequence, however, that viral agents elicit a different tissue response in a given organ than do pathogenic bacteria These differences are found not only in the parenchy-

and antibiotics of therapeutic usefulness in human disease and are presumed to divide by binary fission There is unanimity of opinion that agents of this group are more closely related to rickettsiae than to other viruses, all of which are smaller in size The smallest of the viruses, i e, that causing foot and mouth disease, is almost as minute as the larger protein molecules (cf Fig 1, Chap 2)

As might be anticipated, the larger viruses are more complex structurally, antigenically and biochemically than the smaller ones The elementary bodies of vaccinia, which are the virus particles themselves, appear on electron microscopy as cuboidal objects with dimensions of about 210 × 260 mμ, granules, presumably composed of nucleoprotein, lie in a homogeneous cytoplasm which is surrounded by a membrane The virus particles contain at least 5 different antigens Proteins, lipid, deoxyribonucleic acid (DNA) and copper are constituents of vaccinia virus, while biotin and flavin are probably integral components of the virus (cf. Chap 32). Poliovirus is the best characterized of the small mammalian viruses. It is a spherical particle, almost 25 mμ in diameter, composed of protein and ribonucleic acid (RNA) and containing at least 2 antigens (cf. Chaps 22 to 24).

Probably the most exciting aspects of modern virology are those concerned with the nature of the processes by which new infectious viral particles are formed These processes appear, at first glance at least, to bear little relationship to the classic form of reproduction with the mating of male and female elements, cellular division following pairing of chromosomes and transmission of hereditary characters according to Mendelian laws Neither do they resemble the division of somatic cells which in a simplified form operates in the binary fission of bacteria and rickettsiae. The brilliant investigations dealing with replication of bacteriophages, tobacco mosaic virus, the myxoviruses and others are recounted in a fascinating manner in the several chapters by Hershey, Stanley et al, Hirst and Cohen; the reader is urged to consult these detailed presentations The present discussion will only epitomize a few of the more pertinent developments.

Some of the most imaginative work in biology during the past decade has resulted from the efforts of those studying the bacterial viruses The salient points dealing with replication are as follows: the sperm-shaped bacteriophage attaches itself to the bacterial wall by the tip of its tail, then after digesting away a portion of the wall, it injects its nucleic acid core into the bacterium, leaving the empty protein shell outside the organism. During the few minutes when infectious phage is not detectable in the newly parasitized cell, the phage nucleic acid reduplicates itself manyfold while almost simultaneously the specific phage proteins that make up the coat are produced in abundance. For this process, the phage employs the energy apparatus of the bacterium, which remains functional but substitutes manufacture of viral DNA and protein for creation of new bacterial protein, DNA and RNA Somehow the subunits of phage, i e, the nucleic acid strands and the protein coats, are assembled and result in infectious particles (cf Chaps. 4 and 7).

Tobacco mosaic virus, the filtration of which in the last century introduced the concept of filterable viruses, has continued to provide a model system with which fundamental contributions have been made to biology With this, the first of the viruses to be highly purified, crystallized and shown to consist solely of RNA and protein, it now appears that under proper experimental conditions the nucleic acid alone can infect cells The protein of the virus serves as a protective tube around the fragile nucleic acid filament during its journey from one intracellular environment to another (cf Chap 2, Fig 13)

Influenza viruses and their relatives have provided excellent models for examining the replication process in mammalian viruses These medium-sized viruses, the basic constituents of which are ribose nucleic acid, protein and lipid, contain at least 2 antigens, i e, a nucleoprotein "S" antigen and a protein hemagglutinin. Using the tools of modern virology such as electron microscopy, radioactive compounds and fluorescent antibody, as well as the older technics, it has been possible to trace the events from the time infectious virus enters the cell until other infectious particles emerge. The virus particle disintegrates on reaching the cytoplasm Several hours later, S antigen has increased manyfold in the nucleus and has begun to spread

out into the cytoplasm Shortly after the obvious increase in S antigen, appreciable amounts of hemagglutinin become discernible in the cytoplasm The two subunits move toward the cell wall where the hemagglutinin is assembled around the S antigen and lipid is incorporated to make the finished infectious particle (cf. Chap. 4 and Figs 34 to 38).

Since the nucleic acids of phage, tobacco mosaic virus and other viruses as well constitute the unadorned infectious principal, they are of great interest not only to virologists but also to biochemists and geneticists For example, the former see such nucleic acids as tools for studying the production of proteins, i.e., those specific proteins which eventually form the protective cover for the infectious material, as well as proteins which in some instances have enzymatic activity The latter regard them as among the simplest packages capable of carrying genetic information and hope from elucidation of nucleic acid replication and function in viruses to gain insights applicable to genes in higher organisms Incidentally, the viral nucleic acids behave in *some respects like the DNA of pneumococci* and other bacteria which cause genetic transformation, but perhaps are more aggressive in that they enslave a totally unrelated host cell and usually work it to death in the course of producing quantities of new virus. The bacterial transforming substances, on the other hand, capture closely related organisms and force them to produce progeny like the original organism which supplied the factor

Mutants appear during viral multiplication and are recognized by a variety of distinguishing characteristics Among phages, such markers which are conveniently used in genetic studies are varying plaque types and differing bacterial host ranges, while among influenza viruses antigenic peculiarities, virulence and physical properties provide means for recognizing individuality When infection is induced by two readily distinguishable mutants, most of the progeny resemble one or the other parent, but some individual progeny possess the markers of each parent The last are called recombinants. Perhaps even more interesting is the observation that infection with one mutant in the presence of inactivated particles of another mutant can result in a proportion of infectious progeny with certain markers from the inactivated material. This phenomenon is discussed in a number of later chapters, particularly 3, 4 and 7.

The fact that viruses undergo mutations either in nature or in the laboratory is of practical, as well as theoretical, importance. Thus, the 17D strain of yellow fever virus, which provides one of the most useful live attenuated vaccines available to preventive medicine, is quite different in many respects from its parent strain (cf Chap. 15). The modern methods for obtaining clones of viruses, particularly the plaque and terminal dilution technics, have made it possible to proceed rather rapidly and with considerable assurance in the search for highly attenuated, reasonably stable mutants of the polioviruses for use in a live vaccine That mutants can be disadvantageous to man is illustrated by influenza (cf. Chap 31) The pandemic of 1957 was caused by the Asian strain of influenza A virus which was appreciably different antigenically from other known strains Furthermore, the vast majority of the world populations had no previous experience with this particular strain and hence were susceptible

PATHOLOGY

Because virology, from its inception, has been concerned with disease, and because most of the early mammalian virologists were trained pathologists, the lesions which characterize the infections have received much attention. The pathologic picture of each d[illegible] ilarity of the lesions found in a given organ system, even though these are caused by *different viral or rickettsial agents* Thus, the gross and the microscopic findings in pneumonias caused by influenza or psittacosis viruses, or the rickettsia of Q fever, present more common features than differences The same may be said for the viral encephalitides and for the typhus-spotted fever group of rickettsial diseases This should not be surprising since the pathologist requires bacteriologic aid to differentiate most of the bacterial pneumonias from one another. It is of some consequence, however, that viral agents elicit a different tissue response in a given organ than do pathogenic bacteria These differences are found not only in the parenchy-

matous cells (see below) but also in the cellular infiltrations. The polymorphonuclear leukocyte is the principal cell in the acute inflammation caused by pyogenic bacteria, while mononuclear cells and lymphocytes characterize the secondary inflammatory reaction of the uncomplicated viral lesion

Rivers pointed out in an earlier edition of this book that the primary responses of the *infected cells in all viral maladies are* hyperplasia alone, hyperplasia followed by necrosis, and necrosis alone Examples of viral lesions in which each of these three primary responses predominate are sarcomas produced in the chicken by the Rous agent, pocks on the chorio-allantoic membrane caused by vaccinia virus, and necrosis of anterior horn cells resulting from infection with poliovirus If action of a virus is not extremely rapid and explosive, and if susceptible cells are capable of multiplication, the primary effect of the active agent is stimulation leading to cellular hyperplasia Following the hyperplasia there is usually destruction or necrosis of the cells, which in turn is attended or followed by a secondary inflammation representing a reaction of the neighboring tissues and of the host The balance between the stimulative and destructive tendencies of a virus determines whether hyperplasia or necrosis is the predominant part of the pathologic picture If the action of a virus is explosive or rapid, or if the susceptible cells are incapable of division and multiplication, then the primary pathologic changes are necrobiosis and lysis of cells.

The capacity of viruses to stimulate hyperplasia of cells has an important bearing on the etiology of benign and malignant tumors Although the viral origin of the chicken sarcoma was demonstrated by Rous in 1911 and subsequent years have seen the addition of a variety of tumors of mammals, birds and poikilothermic vertebrates to the list of those caused by viral agents, the only human tumors now known to be of viral etiology are warts The recent advances in virologic knowledge

cancers.

At one time, inclusion bodies were of great importance in viral work and were used for diagnostic purposes. Negri bodies are still important for this reason, but most of the others have become less significant, because more accurate methods of making diagnoses and identifying viruses have been developed. Investigators studying replication of viruses by means of electron microscopy of thin tissue sections and by fluorescent antibody technics have added to the earlier body of data on inclusions which was obtained by microscopic examination of ordinary histologic material *stained with aniline dyes*. Some of the classic inclusions are found only in the cytoplasm and others only in the nucleus, while a few occur in both the nucleus and the cytoplasm For example, Guarnieri bodies of vaccinia, Bollinger bodies of fowlpox, and Negri bodies of rabies are found only in the cytoplasm, the inclusion bodies of herpes simplex and chickenpox occur only in nuclei, and the inclusions of smallpox and paravaccinia are situated in both the nucleus and the cytoplasm Not only does the location of inclusion bodies vary, but their composition and staining reactions may be quite diverse. A Bollinger body consists of a lipoid membrane derived from the host cell and filled with elementary or Borrel bodies embedded in a matrix Guarnieri bodies consist of altered host-cell material in which are embedded many but not all the elementary or Paschen bodies within the cell An intranuclear inclusion is usually an acidophilic mass occupying most of the nuclear area and is surrounded by a clear zone or halo, the basophilic chromatin of the nucleus marginates on the nuclear membrane Recent electron microscopic studies of cells infected with herpes simplex virus have been interpreted as indicating that a small primary body, about 40 mμ in size, differentiates within the nucleus and acquires a limiting membrane These

Similar studies seem to indicate that the elementary bodies of vaccinia and of fowlpox develop entirely in the cytoplasm of infected cells On the other hand, adenovirus particles develop within the nucleus of infected cells, and groups of these particles often form crystalline structures in the nucleus (cf Chap 2, Fig 15). It is evident that the newer methods have added to knowledge of viral inclusions and cytopathology, but much remains to be done in integration of ultramicroscopic and microscopic data

In the typhus-spotted fever group of rickettsial diseases, the primary pathologic lesions are in the small blood vessels where

rickettsiae multiply in the endothelial cells which undergo proliferative and degenerative changes. Secondary inflammatory infiltrations of mononuclear and lymphocytic cells occur in the adventitia of affected vessels. The scattered localized vascular changes with their resultant lesions in adjacent parenchymatous tissues are found throughout the body but particularly in the heart, the lungs and the brain.

Toxic substances are intimately associated with a number of rickettsial and viral agents. These kill mice within a few hours when concentrated suspensions of the microbial agents are injected. Pathologic examination of such animals reveals little except intense vascular congestion. Physiologic studies, particularly in mice affected by the rickettsial toxins, have shown that the basic lesion is increased permeability of capillaries. This results in a series of changes including perivascular edema, hemoconcentration, and eventually death from hypotensive shock. As yet, the role the toxic materials play in the clinical and pathologic pictures of the viral and rickettsial diseases of man is not known.

IMMUNITY AND RESISTANCE

The basic principles of immunology and serology apply in viral and rickettsial diseases just as they do in other fields of medicine and biology. Broadly speaking, virology has been a consumer rather than a creator of serologic technics and of knowledge regarding fundamentals of immunology. Nevertheless, virology contributed one of the most sensitive serologic procedures, i.e., the neutralization test, before the end of the last century and more recently the hemagglutination-inhibition test which has such wide applicability. Moreover, the first of the successful vaccines, i.e., that against smallpox, was described by Jenner almost a century before filterable viruses were recognized as such. Chapter 10 presents in some detail those aspects of serology which are of particular concern to the student of virology, and the chapters dealing with individual diseases discuss many of the immunologic phenomena which are of special importance in these maladies. The excellent chapter "Defense Mechanisms of the Host" by MacLeod in the companion volume, *Bacterial and Mycotic Infections of Man*, should be consulted for general information on the subject and the role of immune mechanisms in the processes of defense.

The early virologists were preoccupied with susceptibility and resistance of various hosts and tissues to the agents under investigation. This is understandable since these workers were able to recognize the presence of their viral agents only indirectly by means of the obvious lesions they produced. That the subject is still of importance is attested by the fact that each chapter in this book which deals with a specific agent has a section entitled "Experimental Infection, Host Range." However, in recent years it has become increasingly evident that many of the viral agents which were originally regarded as extremely limited in their tropism can multiply in organs where they elicit trivial or nonspecific lesions and can be adapted to growth in a variety of tissues and hosts. Poliomyelitis virus illustrates this, for many years it was classified as a highly neurotropic virus the host range of which was limited to primates. Now it is established that the virus multiplies in a variety of tissues in man and monkey, including those of the pharynx, the intestine and the lymph nodes, moreover, involvement of the central nervous system actually occurs in only a small proportion of persons who become infected. Furthermore, all three types of poliovirus grow profusely in tissue cultures prepared from a number of different kinds of cells, while strains of several types have been adapted to growth in embryonated eggs and mice.

The natural resistance of members of a given animal species to a given viral agent is a poorly understood phenomenon though one of great importance. Such resistance, which is unaccompanied by previous experience with the microbial agent, and hence unassociated with antibody immunity, is affected by age, sex, genetic background, state of nutrition, hormonal balance and other factors. The high degree of susceptibility of newborn mice to fatal infection with the Coxsackie viruses and the great resistance of adult mice to this group of agents provide one example of an effect of increasing age on resistance. The influence of hormonal imbalance on natural resistance is illustrated by the effect of pretreatment with cortisone which renders adult mice susceptible to Coxsackie viruses. The possible role of

matous cells (see below) but also in the cellular infiltrations. The polymorphonuclear leukocyte is the principal cell in the acute inflammation caused by pyogenic bacteria, while mononuclear cells and lymphocytes characterize the secondary inflammatory reaction of the uncomplicated viral lesion

Rivers pointed out in an earlier edition of this book that the primary responses of the infected cells in all viral maladies are hyperplasia alone, hyperplasia followed by necrosis, *and necrosis alone Examples of viral lesions* in which each of these three primary responses predominate are sarcomas produced in the chicken by the Rous agent, pocks on the chorio-allantoic membrane caused by vaccinia virus and necrosis of anterior horn cells resulting from infection with poliovirus If action of a virus is not extremely rapid and explosive, and if susceptible cells are capable of multiplication, the primary effect of the active agent is stimulation leading to cellular hyperplasia. Following the hyperplasia there is usually destruction or necrosis of the cells, which in turn is attended or followed by a secondary inflammation representing a reaction of the neighboring tissues and of the host The balance between the stimulative and destructive tendencies of a virus determines whether hyperplasia or necrosis is the *predominant part of the pathologic picture. If* the action of a virus is explosive or rapid, or if the susceptible cells are incapable of division and multiplication, then the primary pathologic changes are necrobiosis and lysis *of cells.*

pla
the

Although the viral origin of the chicken sar*coma was demonstrated by Rous in 1911 and* subsequent years have seen the addition of a variety of tumors of mammals, birds and poikilothermic vertebrates to the list of those caused by viral agents, the only human tumors *now known to be of viral etiology are warts* The recent advances in virologic knowledge about the leukemias of chickens and mice and the discovery of a filterable agent capable of eliciting a number of different kinds of malignant tumors in a single mouse have reactivated a ferment of interest in the search for viruses which may be responsible for certain human cancers.

At one time, inclusion bodies were of great importance in viral work and were used for diagnostic purposes. Negri bodies are still important for this reason, but most of the others have become less significant, because more accurate methods of making diagnoses and identifying viruses have been developed. Investigators studying replication of viruses by means of electron microscopy of thin tissue sections and by fluorescent antibody technics *have added to the earlier body of data on inclusions which was obtained by microscopic* examination of ordinary histologic material stained with aniline dyes Some of the classic inclusions are found only in the cytoplasm and *others only* in the nucleus, while a few occur in both the nucleus and the cytoplasm For example, Guarnieri bodies of vaccinia, Bollinger bodies of fowlpox, and Negri bodies of rabies are found only in the cytoplasm; the inclusion bodies of herpes simplex and chickenpox occur only in nuclei, and the inclusions of smallpox and paravaccinia are situated in both the nucleus and the cytoplasm. Not only does the location of inclusion bodies vary, but their composition and staining reactions may be quite diverse A Bollinger body consists of a lipoid membrane derived from the host cell and filled with elementary or Borrel bodies embedded in a matrix Guarnieri bodies consist of altered host-cell material in which are embedded many but not all the elementary or Paschen bodies within the cell An intranuclear inclusion is usually an acidophilic *mass occupying most of the nuclear area and* is surrounded by a clear zone or halo, the basophilic chromatin of the nucleus marginates on the nuclear membrane Recent electron microscopic studies of cells infected with herpes simplex virus have been interpreted

small particles, on release into the cytoplasm, *acquire a second* surrounding membrane and a diameter of about 120 mμ, the larger particles presumably represent infectious virus Similar studies seem to indicate that the elementary bodies of vaccinia and of fowlpox *develop entirely in* the cytoplasm of infected cells On the other hand, adenovirus particles develop within the nucleus of infected cells, and groups of these particles often form crystalline structures in the nucleus (cf. Chap 2, *Fig 15) It is evident that the newer meth*ods have added to knowledge of viral inclusions and cytopathology, but much remains to be done in integration of ultramicroscopic and microscopic data.

In the typhus-spotted fever group of rickettsial diseases, the primary pathologic lesions are in the small blood vessels where

current attack of labial herpes, or finally it may be shed, as by the typhoid carrier, and contaminate the environment. When the agent and the animal cell exist in a state of mutual tolerance, such as occurs in lysogenic bacteria, the pathogen can be transmitted to daughter cells presumably in the immune animal and certainly in experimentally infected tissue cultures. While the persistence of viral and rickettsial agents in recovered man and animals is undoubtedly of great interest and importance from a number of points of view, including long-term immunity, such a mechanism need not necessarily be evoked to explain the permanent immunity which characterizes many viral diseases.

MacLeod pointed out in 1952 that a number of viral, bacterial and fungal diseases characterized by permanent immunity have incubation periods of a week or more. He suggested that in these diseases the rapid secondary immune response might be one of the factors concerned with the failure to have a second classical attack of the malady. Although infection might occur on re-exposure to the viruses of measles, mumps and other long incubation diseases, the recall immune reaction would be expected to augment resistance during the incubation period and result in suppression of overt disease. He also noted that the recall mechanism would not have time to become operative in diseases with incubation periods of less than 3 days, such as the common cold and influenza which are characterized by repeated attacks. Quite a different approach to an explanation for the persistence of immunity and antibodies has been postulated by a number of workers. This employs a variety of hypotheses to account for the continuing presence in the cell of a model for synthesizing antibody that remains active long after the original antigen has been disposed of. Treffers' chapter "Serology and Immunochemistry" in the companion volume *Bacterial and Mycotic Infections of Man* discusses these ideas which lean heavily on templates, self-replicating enzymes and current hypotheses about synthesis of normal proteins. Irrespective of the explanation, the fact remains that antibodies against certain noninfectious antigens, for example, tetanus toxoid, continue to be detectable in the serum of man for years after a course of immunization; here the possibility of contact with the antigen under natural conditions, as in recurrent epidemics of measles, is negligible. It is evident that persistent immunity can result from several mechanisms and it is likely that more than one is operative in many infections.

In discussing the absence of durable immunity in certain viral and rickettsial diseases, it is necessary to recall that the clinical manifestations which characterize the maladies may be caused by a group of related but antigenically dissimilar agents. Detailed information on the types and the strains of pathogens associated with the common cold, influenza, poliomyelitis, Coxsackie infections, dengue and scrub typhus is given in the chapters which deal with these diseases. In some instances the several agents are so dissimilar that infection with one elicits essentially no immunity to another even under experimental conditions, for example, influenza A and C or polio Types I and III. In other instances, notably in dengue and in scrub typhus, the distinguishable strains or types of the etiologic agents elicit complete resistance in man to the homologous pathogen for at least several years but to the heterologous members of the group for only a month or so. In the last two diseases, inoculation of recovered volunteers with heterologous strains after 3 months produces an abortive or atypical illness, but after a year results in a second episode of the classical disease.

The original infection of man with certain viruses almost invariably results in the classical features of the disease, smallpox, measles, chickenpox and rabies provide illustrative examples of this. In contrast, infection with certain other viruses rarely produces the textbook description of the full-blown malady. Thus only a small proportion of persons infected with poliovirus develop paralytic disease, and few persons who become infected with St. Louis, western, or Japanese encephalitis virus display signs of encephalitis. Nonparalytic poliomyelitis or aseptic meningitis occurs in some people infected with the viruses just mentioned, but the majority suffer a subclinical or brief, poorly defined illness. The active immunity which develops in persons following such subclinical or mild infections differs in no way from that found in patients convalescent from severe illness.

properdin and other similar humoral factors in natural resistance of animals to viral infections deserves careful study.

The interference phenomenon is concerned with a cell, animal, or plant which on exposure to viral material promptly develops resistance to infection by virus. The reaction itself is unrelated to classic immunologic responses, although it impinges on and interdigitates with immunologic reactions as is evident from certain of the examples of interference which are cited below. Lysogenic bacteria, i.e., those latently infected with a temperate phage which are capable of growing and multiplying, are resistant to destruction by virulent strains of the homologous phage even though fully susceptible to virulent strains of other phages. Along similar lines, cells treated with noninfectious influenza virus promptly lose susceptibility to active homologous virus. The interference phenomena also extend to the intact animal. Thus, monkeys inoculated peripherally with nonlethal amounts of a neurotropic strain of yellow fever virus will, within a few hours, resist a fatal dose of viscerotropic yellow fever virus. Interference is not limited to homologous or even closely related viruses. For example, monkeys infected with the virus of lymphocytic choriomeningitis are for a short time less susceptible than normal animals to the destructive effects of poliovirus, and, similarly, mice injected intracerebrally with influenza virus resist lethal amounts of the virus of western equine encephalomyelitis. The mechanism of interference is poorly understood. Although there has been hope that the phenomenon might be applicable to measures for the prevention of human disease, this has not yet been realized. However, interference may be of some importance in nature in the geographic limitation of certain arthropod-borne infections. The viruses of yellow fever and dengue interfere with one another in their common vector *Aedes aegypti*; since infection persists for life in such mosquitoes, a naturally infected Aedes presumably would be incapable of transmitting more than one of the agents (cf. Chap. 5).

Active immunity is the state of resistance engendered by a spontaneous attack of an infectious disease, whether classic, atypical or subclinical in its manifestations, by the experimental or intentional production of the disease or a modified form of it or by the injection of a vaccine. In a number of viral and rickettsial diseases, just as in some bacterial and fungal diseases, one attack almost invariably confers lifelong immunity; examples of this are smallpox, measles, mumps, poliomyelitis, yellow fever and epidemic typhus. Most persons recovered from the maladies just mentioned continue to have demonstrable specific circulating antibodies for many years after an attack. Since certain of these diseases, i.e., measles, mumps and polio, are present at frequent intervals in a community, one might account for the persistent immunity and continual presence of humoral antibodies on the basis of repeated contacts with the viral agents and several subclinical attacks. On the other hand, this explanation is inadequate to account for persistent antibodies in persons who recover from yellow fever or typhus and then live many years in the U.S.A. or other areas where these diseases are not endemic. It is often assumed in such instances that the agent persists in the recovered individual just as it does in the typhoid carrier. The best clinical example of such persistence is Brill-Zinsser disease which is a recurrent form of epidemic typhus developing long after the initial attack (cf. Chap. 42). Sufficient instances in which viruses have been recovered from immune hosts have been recorded to show that it is not an unusual occurrence, for example, the demonstration of herpes simplex virus in the gasserian ganglion, of adenoviruses in tonsillar tissue and salivary gland virus in the urine of children many months after initial infection, as well as the finding of psittacosis virus in birds and man, infectious anemia virus in horses and lymphocytic choriomeningitis virus in mice, long after apparent recovery.

The mechanism by which these pathogens survive in the immune hosts is not understood. They exist intracellularly, where they are protected from the usual humoral and phagocytic defense mechanisms of the animal, and presumably maintain a state of parity in a cold war with the cell. When the pathogen gains supremacy and the infected cell is destroyed, the liberated agent may fall prey to the defenses of the host and incidentally stimulate its immunologic mechanism, or it may induce Brill-Zinsser disease or a re-

current attack of labial herpes, or finally it may be shed, as by the typhoid carrier, and contaminate the environment. When the agent and the animal cell exist in a state of mutual tolerance, such as occurs in lysogenic bacteria, the pathogen can be transmitted to daughter cells presumably in the immune animal and certainly in experimentally infected tissue cultures. While the persistence of viral and rickettsial agents in recovered man and animals is undoubtedly of great interest and importance from a number of points of view, including long-term immunity, such a mechanism need not necessarily be evoked to explain the permanent immunity which characterizes many viral diseases.

MacLeod pointed out in 1952 that a number of viral, bacterial and fungal diseases characterized by permanent immunity have incubation periods of a week or more. He suggested that in these diseases the rapid secondary immune response might be one of the factors concerned with the failure to have a second classical attack of the malady. Although infection might occur on re-exposure in the viruses of measles, mumps and other long incubation diseases, the recall immune reaction would be expected to augment resistance during the incubation period and result in suppression of overt disease. He also noted that the recall mechanism would not have time to become operative in diseases with incubation periods of less than 3 days, such as the common cold and influenza which are characterized by repeated attacks. Quite a different approach to an explanation for the persistence of immunity and antibodies has been postulated by a number of workers. This employs a variety of hypotheses to account for the continuing presence in the cell of a model for synthesizing antibody that remains active long after the original antigen has been disposed of. Treffers' chapter 'Serology and Immunochemistry' in the companion volume *Bacterial and Mycotic Infections of Man* discusses these ideas which lean heavily on templates, self-replicating enzymes and current hypotheses about synthesis of normal proteins. Irrespective of the explanation, the fact remains that antibodies against certain noninfectious antigens, for example, tetanus toxoid, continue to be detectable in the serum of man for years after a course of immunization, here the possibility of contact with the antigen under natural conditions, as in recurrent epidemics of measles, is negligible. It is evident that persistent immunity can result from several mechanisms and it is likely that more than one is operative in many infections.

In discussing the absence of durable immunity in certain viral and rickettsial diseases, it is necessary to recall that the clinical manifestations which characterize the maladies may be caused by a group of related but antigenically dissimilar agents. Detailed information on the types and the strains of pathogens associated with the common cold, influenza, poliomyelitis, Coxsackie infections, dengue and scrub typhus is given in the chapters which deal with these diseases. In some instances the several agents are so dissimilar that infection with one elicits essentially no immunity to another even under experimental conditions, for example, influenza A and C or polio Types I and III. In other instances, notably in dengue and in scrub typhus, the distinguishable strains or types of the etiologic agents elicit complete resistance in man to the homologous pathogen for at least several years but to the heterologous members of the group for only a month or so. In the last two diseases, inoculation of recovered volunteers with heterologous strains after 3 months produces an abortive or atypical illness, but after a year results in a second episode of the classical disease.

The original infection of man with certain viruses almost invariably results in the classical features of the disease; smallpox, measles, chickenpox and rabies provide illustrative examples of this. In contrast, infection with certain other viruses rarely produces the textbook description of the full-blown malady. Thus only a small proportion of persons infected with poliovirus develop paralytic disease, and few persons who become infected with St. Louis, western, or Japanese encephalitis virus display signs of encephalitis. Nonparalytic poliomyelitis or aseptic meningitis occurs in some people infected with the viruses just mentioned, but the majority suffer a subclinical or brief, poorly defined illness. The active immunity which develops in persons following such subclinical or mild infections differs in no way from that found in patients convalescent from severe illness.

Associated in most instances with the development of active immunity against viruses in recovered persons is the appearance of circulating antibodies What relation do such antibodies have to immunity against virus diseases? Animals may possess agglutinins, precipitins and complement-fixing antibodies against certain viruses without being resistant to infection In most instances, but not all, the presence in an animal's serum of neutralizing antibodies against a virus indicates that such an animal is resistant to the active agent. However, some animals recovered from a virus infection are resistant to reinfection without possessing demonstrable neutralizing antibodies.

Passive immunity is a state of resistance to infection produced in a normal person by the parenteral administration of serum containing antibodies, such sera are obtained from actively immunized persons or animals So far as is known, this state of resistance to virus diseases can be brought about only by the injection of serum containing neutralizing antibodies. In passive immunity it is quite obvious that humoral antibodies are the important factors rather than tissue immunity Whether the antibodies introduced into people protect susceptible cells against the entry of virus, whether they act directly on the virus in such a manner as to prevent the production of disease, or, finally, whether they enhance the destruction of virus by certain phagocytic cells, is not known Passive immunity is of great practical interest because of its use in connection with prophylaxis and treatment of virus diseases, a matter discussed later in this chapter

Immunologic principles derived from studies on skin grafting which deal with acquired tolerance may have applicability in certain aspects of viral infections Such tolerance has been defined as an induced state of nonreactivity toward a substance that is normally antigenic—due to a primary failure of the machinery of the immunologic response. Contrary to the usual experience, adult animals will accept skin grafts from distant relatives if prepared by an inoculation of similar tissue given before the immunologic response comes into being at about the time of birth Mice which survive intra-uterine infection with the virus of lymphocytic choriomeningitis appear healthy but have viremia for months after birth without developing an antibody response. On the other hand, mice infected as adults behave in the customary manner developing antibodies after a period of systemic involvement (cf Chap. 46) It has been suggested that the principle of acquired tolerance might be considered in explaining the paradox just described The possibility has not been probed that a similar mechanism is operative in the prolonged viremias that occur in human beings and horses infected with the viruses of serum hepatitis and infectious anemia, respectively

TRANSMISSION

The viruses which cause most of the world-wide epidemic diseases of man have as their sole natural host man himself, hence, human beings serve as the reservoir for the agents Transmission of diseases such as measles, smallpox, poliomyelitis and other members of this group is usually by contact with infected persons (direct) or with their immediate environment which has been contaminated (indirect) Transmission by droplet spread is perhaps best considered as a form of contact infection since it involves reasonably close association between the patient who sneezes or coughs and the susceptible person The source of infectious materials in the measles patient is secretion from the nose and the throat and transmission of this highly communicable disease is by droplet spread and direct contact. In smallpox, the lesions of the skin and mucous membranes, as well as respiratory discharges, are sources of virus for spread by contact, by aerial transmission and by contaminated articles (fomites). Poliovirus appears in the feces and the pharyngeal secretions of infected persons and is transferred directly from hand to mouth and by droplets Details regarding transmission of these and other diseases with similar modes of spread can be found in appropriate chapters in this book

Many of the viral and most of the rickettsial diseases are transmitted to man by arthropods (mosquitoes, lice, fleas, mites, ticks and sandflies). However, in only a few of these does man serve as the reservoir. Urban yellow fever, in contrast with jungle yellow fever,

and epidemic typhus are examples in which the maladies are spread from man to man by mosquitoes and lice, respectively. Certain of the human diseases in which arthropods serve as vectors are maintained in nature by infection chains which involve wild animals or birds as principal hosts and reservoirs. Moreover, the arthropod vector also serves as one of the reservoirs in some instances, for example, in scrub typhus and spotted fever where the rickettsiae are passed transovarially in the mite and the tick, respectively, from one generation to the next. In these cycles in nature, man is only an accidental participant. Indeed, when infected he usually does not reinfect vectors and perpetuate the transmission; illustrative examples are Colorado tick fever and murine typhus as well as the two rickettsial diseases mentioned in the preceding sentence. On the other hand, the individual who contracts yellow fever in the jungle from the bite of a Haemagogus mosquito that acquired the virus from an infected monkey can, on becoming ill with viremia in a community infested with *Aedes aegypti*, start an epidemic of urban yellow fever which will spread as long as susceptibles are available and Aedes persist. The ecology and the epidemiology of the vector-transmitted diseases are frequently complicated and sometimes unique, the appropriate chapters should be consulted for details. Two of the most complex cycles are worthy of mention even though they are not directly concerned with human disease. The virus of swine influenza has the lung worm as an intermediate host, this parasite itself has a complicated cycle and its eggs, on excretion in swine feces, are taken up by earthworms where they develop through several larval stages. The earthworms are in turn eaten by pigs, after which the developing lung worm larvae migrate to the lungs. Throughout the lung worm sojourn the virus remains masked but under appropriate conditions it is released by the parasite in the lung, producing swine influenza. The rickettsialike organism causing the highly fatal salmon poisoning disease of dogs has as an intermediate host an intestinal fluke which in turn has a complex cycle requiring snails, salmonid fish and mammals for maturation, canines develop the disease after eating infected fish.

Very few viral diseases are water-borne, infectious hepatitis being an outstanding example (and even this is not usually spread by water but by contact). Only a few viruses are spread by food, several milk-borne epidemics of poliomyelitis and at least one of infectious hepatitis have been reported. One virus disease, rabies, is ordinarily transmitted only by the bite of a rabid animal.

PREVENTION AND TREATMENT

Three of the 6 human diseases subject to international quarantine regulations are caused by viral or rickettsial agents; these 3 are smallpox, yellow fever and epidemic typhus (the other 3 are plague, cholera and relapsing fever). Although quarantine measures have become highly efficient in limiting the international spread of these ancient pestilences, it is worthy of note that the procedures in each instance go far beyond temporary limitation of freedom of affected and exposed persons. They include, in addition, enforcement of sanitary practices, disinfestation or decontamination, and, in a number of instances, vaccination of susceptibles. On the other hand, because of lack of effectiveness in controlling spread of disease in local communities, quarantine has been abandoned or modified for patients, and their known contacts, with measles, rubella, chickenpox, mumps, poliomyelitis and most other viral infections in which man is the reservoir of the agent.

Immunization procedures provide a shield for the individual and the community against a number of viral and rickettsial diseases. Two vaccines, each containing live attenuated viruses, are among the most important weapons of public health officers, these are smallpox and yellow fever vaccines. When properly used, they are safe, they protect almost every individual, and they promptly stop an epidemic. Three other vaccines which are highly effective, but not so nearly perfect as the two just mentioned, are those against epidemic typhus, influenza and poliomyelitis. Each of these three consists of noninfectious antigen, and each has been administered to millions of persons. In addition, there are vaccines which have an appreciable value but have been employed less widely. In some instances the limited use is dependent on the restricted group of persons at risk, for example, adeno-

Associated in most instances with the development of active immunity against viruses in recovered persons is the appearance of circulating antibodies. What relation do such antibodies have to immunity against virus diseases? Animals may possess agglutinins, precipitins and complement-fixing antibodies against certain viruses without being resistant to infection In most instances, but not all, the presence in an animal's serum of neutralizing antibodies against a virus indicates that such an animal is resistant to the active agent. However, some animals recovered from a virus infection are resistant to reinfection without possessing demonstrable neutralizing antibodies

Passive immunity is a state of resistance to infection produced in a normal person by the parenteral administration of serum containing antibodies, such sera are obtained from actively immunized persons or animals So far as is known, this state of resistance to virus diseases can be brought about only by the injection of serum containing neutralizing antibodies. *In passive immunity it is quite* obvious that humoral antibodies are the important factors rather than tissue immunity Whether the antibodies introduced into people protect susceptible cells against the entry of virus, whether they act directly on the virus in such a manner as to prevent the production of disease, or, finally, whether they enhance the destruction of virus by certain phagocytic cells, is not known Passive immunity is of great practical interest because of its use in connection with prophylaxis and treatment of virus diseases, a matter discussed later in this chapter

tary bodies were as large as certain bacteria and hence were regarded as small living organisms. Then Elford, 1931, began his important work on the filtration of virus preparations through graded collodion membranes of known porosity. He soon established the fact that different viruses possessed different and characteristic sizes and that some viruses possessed diameters of about 10 mμ, while others had diameters of about 300 mμ This work on a physical property, namely size, had a profound influence on the thinking of the times, for investigators began to wonder about the true nature of a structure only 10 mμ in diameter which possessed the ability to replicate or to bring about its replication .

Studies on the chemical properties of viruses also began to assume importance around 1930 Vinson and Petre (1929, 1931) showed that tobacco mosaic virus could be subjected to numerous chemical manipulations with retention of virus activity Many investigators working with different viruses conducted studies on the effect of different chemicals on virus activity Chemical investigations directed toward the concentration and the purification of certain viruses were started One of these led to the isolation, in 1935, of tobacco mosaic virus in the form of a crystalline material of unusually high molecular weight (Stanley, 1935) This material was subsequently shown to be a nucleoprotein with a particle size of

lowed by the isolation of over a dozen viruses in highly purified, and in some instances, crystalline form Recently, poliomyelitis virus (Schaffer and Schwerdt, 1955), Coxsackie virus (Mattern and du Buy, 1956) and an insect virus (Williams and Smith, 1957) were obtained in crystalline form All these purified viruses have been found to be at least as complex as a nucleoprotein with some containing ribose nucleic acid and others deoxyribose nucleic acid. A recent finding of the greatest importance is the discovery by Fraenkel-Conrat (1956), and independently by Gierer and Schramm (1956), that a nucleic acid preparation possessing virus activity can be obtained from tobacco mosaic virus nucleoprotein.

A chart showing the approximate sizes of several viruses and some reference materials, prepared largely from data obtained with the electron microscope, is provided in Figure 1.

PURIFICATION

Chemical Methods of Purification

The purification of a virus by chemical technics involves the use of a procedure or, usually, of a series of different procedures which results in a relative enrichment of virus as measured by biologic assay. It is advisable to determine the pH stability range of the virus under investigation, for chemical treatments involving hydrogen ion concentrations outside of the range of stability of the virus cannot be employed. Another factor of considerable importance is the selection of the starting material. Thus, for example, other factors, such as approximate amount of virus, etc., being equal, it would be better to use the extra-embryonic fluids of the infected chicken embryo rather than an extract of emulsified whole chicken embryo as starting material, for the former contains far less extraneous material than does the latter. Every effort should be made to secure a starting material containing the highest possible concentration of virus and the lowest possible concentration of nonviral materials having properties similar to those of the virus Because viruses differ in their chemical properties, and because the impurities associated with any given virus also differ, it is not possible to outline a definite procedure for the purification of viruses However, because all purified viruses now known are at least as complex as a nucleoprotein, the general methods which have been employed in work with proteins have been found to be valuable in work with viruses Some degree of purification usually can be achieved by treatment with methyl, ethyl or butyl alcohol, or with salts such as ammonium or magnesium sulfate. Generally, increasing amounts of alcohol or salt are added to aliquots of a virus preparation buffered to a definite hydrogen-ion concentration, and the amount of alcohol or salt necessary to precipitate all of the virus activity is determined Any impurities remaining in the supernatant liquid can then be separated from the virus Another general procedure of value involves the adsorption of virus on some material at a given pH or temperature and the separation of this material, plus adsorbed virus, from the bulk of the liquid and accompanying impurities, followed by the elution of the virus from the adsorbent

at another pH or temperature The adsorption of tobacco mosaic virus on celite at pH 4.5 followed by elution at pH 7 (Stanley, 1935), or the adsorption of influenza virus on chicken red blood cells at 4° C (Hirst, 1941; McClelland and Hare, 1941) are examples of the use of this procedure

Different enzymes have been used to digest protein impurities present in virus preparations Of course, it is necessary to demonstrate that the enzyme used does not cause inactivation of the virus It is also necessary to develop a method for separating the enzyme, as well as the digestion products, from the virus Occasionally, iso-electric precipitation, either of the virus or of protein impurities, can be used to good advantage Certain viruses have also been purified by use of immunochemical methods An antiserum to a crude virus preparation is made and then absorbed with extracts of normal materials from the same kind of host used for production of the virus The residual antibodies presumably are for the virus, and from the virus-antibody precipitate the virus can be obtained by dissociation or in some cases by removal of the antibody portion by means of enzymatic digestion

Physical Methods of Purification

When chemical methods were used in attempts to purify certain viruses which were less stable than tobacco mosaic virus, the viruses were largely inactivated Consequently, physical methods of purification have been explored extensively, particularly high-speed centrifugation

Vacuum-Type Angle C[illegible]

[illegible] purify vaccinia and fowlpox viruses, it did not gain immed[illegible]

[illegible] knowledge concerning the sizes of various viruses. However, when the approximate sizes of several viruses became known from filtration experiments, it was apparent that viruses could be sedimented readily by centrifugal fields of from 50,000 to 100,000 times gravity

Although the first ultracentrifuges were air driven, high-speed electric drives capable of operating at 50,000 r p m. or more have been developed within the past few years. Suitable bearings for the connection between drive and rotor and for the support of large rotors operated in a vacuum chamber have also been developed so that these high-speed drives have largely replaced the air turbine.

The rotor is so designed that, while rotating in a high vacuum, its contents are at atmospheric pressure. Since the rotor spins in a vacuum, there is little friction, and very little heat is generated For use with unstable viruses, the rotor may be cooled to about 0° C., and the material may be kept cold during the entire centrifugation process

Fortunately, in the cases of several viruses, starting materials have been found in which the impurities have rates of sedimentation quite different from that of the virus. In these cases the starting material is first centrifuged at a speed and for a length of time sufficient to sediment practically all materials which migrate more rapidly than the virus The supernatant liquid is then removed and centrifuged at a speed and for a length of time necessary to sediment all or most of the virus The supernatant liquid is discarded, and the pellets of virus, which are usually small and opalescent, are suspended in a liquid known to provide a favorable environment. Subsequent cycles of differential centrifugation are then employed until tests indicate that practically all light and heavy impurities have been removed

The method of differential centrifugation has been used to purify the viruses of tobacco mosaic (Wyckoff et al , 1937) potato latent [illegible]

[illegible] (Ross, 1941a), equine encephalomyelitis (Taylor et al , 1943a), influenza (Taylor et al , 1943b, Stanley, 1944a, Sharp et et , 1944b), Lansing poliomyelitis (Loring and Schwerdt, 1946, Schaffer and Schwerdt, 1955), Southern bean mosaic (Price, 1946), Newcastle disease (Bang, 1946, Cunha et al , 1947), polyhedral disease of silkworm (Bergold, 1947), potato yellow-dwarf (Brakke et al , 1951), wound tumor (Brakke et al, 1954), Coxsackie (Mattern and du Buy, 1956), avian myeloblastic leukosis (Beard, 1956), avian erythroblastosis (Beard et al , 1957) and *T paludosa* [illegible]

as [illegible]

And [illegible] of Japanese B encephalitis in mouse brains (Duffy and Stanley, 1945), considerable difficulty was encountered, for the extracts of the

FIG. 2. Crystals of tobacco-mosaic virus (×675) (Stanley, W. M., 1937. Crystalline tobacco-mosaic virus protein, Am. J. Botany *24*, 59-68)

normal host were found to contain material which sedimented at a rate near that of the virus. If it is assumed that materials of the normal hosts will also be present in the extracts from the diseased hosts, it is obvious that such impurities could never be separated from the viruses by means of differential centrifugation. Other means, such as immunochemical procedures, must be employed to separate impurities of this type.

It should be emphasized that purification by means of differential centrifugation is especially suitable for unstable viruses, since the operations can be conducted quickly and in the cold (Stanley and Wyckoff, 1937). It seems likely that this method will continue to be used [illegible]

The main difficulty encountered has been a certain amount of stirring within the centrifuge tubes due to convection currents resulting in a small proportion of the virus remaining in the supernatant liquid. This difficulty usually is not serious in connection with purification procedures, since only a small percentage of the virus remains in the supernatant liquid. Of [illegible]

experimentation with continuous-flow types of centrifuge, since these have a considerably larger capacity. Stanley (1942a) reported that large amounts of purified tobacco mosaic virus could be prepared by means of the commercially available Sharples Laboratory Supercentrifuge equipped with the regular clarifier bowl operated at a speed of 50,000 r.p.m. by means of compressed air. Stanley (1944a) and later Taylor et al. (1945) demonstrated that influenza virus in the extra-embryonic fluids of infected chick embryos could be purified by means of the Sharples centrifuge. In the cases of the PR8 and Lee strains, about 85 to 90 per cent of the virus could be recovered in the sediment in the bowl at rates of flow around 50 cc. per minute. Because of the effi-

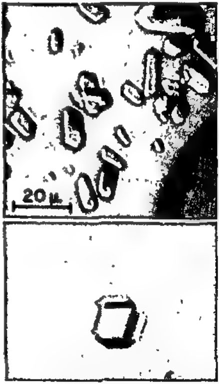

FIG. 3. (*Top*) Crystals of MEF-1 poliomyelitis virus. (Schaffer, F. L. and [illegible]

phys. acta *28*, 241-246)

ciency and the ease of this process, and because of the purity of the product, this method has been adopted for the commercial production of purified influenza virus for use in vaccines (Stanley, 1945). The method has been employed by Randall et al (1947) for the purification of Japanese B encephalitis virus Cox et al (1947) found that alcohol precipitation, followed by continuous-flow centrifugation, provides an efficient method for working with very large volumes of extra-embryonic fluid in the production of influenza vaccine

During recent years a combination of chemical and physical procedures has been used quite successfully for the purification of several viruses These have yielded crystalline preparations of turnip yellow mosaic virus (Markham and Smith, 1949, Cosentino et al, 1956), tobacco ring spot virus (Steere, 1956), poliomyelitis viruses (Schaffer and Schwerdt, 1955, Schwerdt and Schaffer, 1956) and Coxsackie virus (Mattern and du Buy, 1956) Crystals of tobacco mosaic, the first virus to be obtained in crystalline form, are shown in Figure 2, and crystals of poliomyelitis virus, the first animal virus to be obtained in crystalline form, are shown in Figure 3.

IDENTIFICATION OF VIRUS WITH PURIFIED PRODUCTS

Chemical Fractionation

When a supposedly purified product has been obtained, it is necessary to prove that the material in question actually consists of virus and not of a mixture of virus and extraneous materials One way of doing this is to subject the purified product to a series of chemical procedures which may result in the separation of the material into two or more fractions. Then these fractions can be tested for their specific virus activity, that is, activity per unit weight, and if the specific virus activity of one fraction is greater than that of other fractions, the results provide definite evidence that the original material actually consisted of a mixture of virus and impurities. However, if all fractions are found to possess the same specific virus activity, the results can be regarded as providing evidence that the purified product is actually the virus It should be emphasized that a series of different types of chemical fractionation procedure should be used, for although a virus and impurity might be fractionated in the same proportion by one procedure, it is highly unlikely that they always would be fractionated in the same proportion by a wide variety of procedures However, failure to secure fractionation of a purified product is only negative evidence, and such tests gain weight only as they are increased in number and in variety (Stanley, 1938a).

One simple method of securing the separation of a purified virus product into two fractions consists of the addition of sufficient ammonium sulfate or magnesium sulfate to cause the precipitation of only part of the purified product. The precipitated material can be separated from the liquid portion by centrifugation or filtration, and the specific virus activity of the two fractions can be determined. This procedure was used in connection with early tests on tobacco mosaic virus, and it was found that the specific virus activity of the two fractions was the same It may be of interest to note that when purified preparations of two strains of tobacco mosaic virus were mixed and subjected to fractionation with salt, an almost complete separation of the strains was accomplished.

It is obvious that other methods of fractionation such as the use of alcohol, acetone, lead acetate or specific antisera, as well as isoelectric precipitation, can be used Another procedure of importance consists of treating the purified product with an adsorbent, such as charcoal, celite or aluminum hydroxide, followed by tests on the adsorbed and the unadsorbed portions of the preparation. In all cases, it is necessary to prove that the procedure used to achieve fractionation does not cause inactivation of the virus However, an important method of testing for homogeneity consists in the deliberate destruction or inactivation of a portion of the purified product, followed by tests for specific virus activity of the remainder. Reagents such as acids, alkalis, urea, enzymes and various detergents, as well as heat or high pressures, can be used for this purpose If the specific virus activity of the remaining portion is the same as that of the starting material, the results can be regarded as providing evidence of homogen-

partial inactivation of the virus or to the preferential destruction of virus in a mixture of virus and impurity

Advantage should be taken of special situations which provide opportunities for fractionation Thus, in the case of influenza virus, adsorption of virus on washed chicken red blood cells provides a means of fractionation With impure preparations of influenza virus, adsorption on chicken red blood cells followed by elution yields a product of higher virus activity However, with highly purified influenza virus preparations the virus activity is unchanged following adsorption on and elution from chicken red blood cells

Physical Fractionation

Since physical methods are in general, somewhat milder than chemical methods, they have been used widely in attempts to fractionate virus preparations The general approach has been similar to that described above for chemical methods The purified virus preparation is subjected to one or more physical processes which result in the separation of the material into two or more fractions, and the specific virus activities of these are then determined Fractionation has been achieved by means of centrifugation electrophoresis, chromatography and filtration through collodion membranes In early work with purified tobacco mosaic virus, Stanley (1937b) centrifuged solutions of the virus at pH 2 4, 6 7 and 9 4, so that about 85 to 95 per cent of the protein was removed from the upper portions of the supernatant liquids, he found that the specific virus activity of the separated upper and lower portions of the solutions was the same Since the iso-electric point of this virus is about pH 3 5, the virus was sedimented on both sides of the iso-electric point, that is, as negatively charged particles and as positively charged particles The results provided a powerful argument against the idea that virus activity is due to an entity adsorbed on the protein or to a dissociable active group attached to the protein

In contrast with centrifugation, which permits fractionation by virtue of movement in a centrifugal field, electrophoresis achieves the same result through movement in an electrical field. If the pH range of stability of a given virus is sufficiently broad, the virus can be caused to migrate as either negatively or positively charged particles If, following movement over appreciable distances and under different conditions of pH, the specific virus activity of different portions of the liquid remains unchanged, it may be concluded that the preparation is homogeneous with respect to electrophoretic mobility Since it is highly unlikely that the virus and an impurity would migrate at exactly the same rate at different pH's, such results can be regarded as strong evidence that the virus preparation is pure Tests of this nature have been made with several virus preparations, including those of tobacco mosaic (Eriksson-Quensel and Svedberg, 1936), rabbit papilloma (Sharp et al, 1942) and influenza (Miller et al, 1944)

Although the sizes of practically all viruses for which there are suitable biologic tests have been estimated by means of ultrafiltration, this technic has not been used extensively for the fractionation of purified virus preparations Whenever the technic has been used, however, it has generally proved to be satisfactory Collodion filters which will just permit the virus to pass or will just retain the virus are used to determine whether or not the preparation contains impurities possessing filtration characteristics different from that of the virus As in the cases of centrifugation and electrophoresis, virus preparations at different hydrogen-ion concentrations can be tested If the material passes through or is retained by filters under the same conditions under which the virus activity passes through or is retained, the results provide evidence that the material in question is actually the virus

CHARACTERIZATION OF VIRUS MATERIALS

Ultrafiltration

The oldest physical procedure employed in the study of viruses is filtration Bacteriologists had learned early that bacteria could be retained by certain types of filters Iwanowski, 1892, observed that the agent responsible for the tobacco mosaic disease was not retained by a filter which would hold back all pathogenic bacteria then known Later in the study of virus diseases, it was found that filters could be produced which would retain viruses

Allard, 1916, found that, even though tobacco mosaic virus would pass through a Berkefeld filter, it was held back by a Livingstone atometer porous cup Since that time, filters graded for pore size have been made available, and these can be used for the determination of the approximate sizes of viruses, Elford, 1931, Ferry, 1936.

In order to determine the size of a virus particle by means of ultrafiltration, one attempts to pass it through a series of filters, graded with respect to pore size Then the size of the virus is related to the size of the pores in the finest filter through which the particles will pass Several complications are encountered in filtration It has been found necessary to use surface tension active substances, such as sodium oleate or nutrient broth, in order to prevent clogging of the filters Even when this is done, some materials known to be smaller than the pores will not pass This is thought to be due, at least in part, to the surface electric charges of the filter and the particles. Elford has shown experimentally that there is no exact correspondence between the average pore size and the size of the particles By passing colloidal particles with dimensions determined by other means through a graded series of filters, Elford (1933) obtained the data presented in Table 1 showing the approximate relationship between pore size and particle size. It can be seen that, for fine filters, the average pore size must be from 2 to 3 times the particle diameter in order for the particles to pass. For filters with large pores there is more nearly exact correspondence between average pore size and the size of the particles which will pass

TABLE 1 THE RELATIONSHIP BETWEEN THE AVERAGE MEMBRANE PORE DIAMETER AND THE RATIO $\frac{\text{PARTICLE DIAMETER}}{\text{PORE DIAMETER}}$

AVERAGE MEMBRANE PORE DIAMETER IN mμ	$\frac{\text{PARTICLE DIAMETER}}{\text{PORE DIAMETER}}$
10- 100	⅓- ½
100- 500	½- ¾
500-1,000	¾-1

Filtration has been applied to the determination of the particle size of many viruses Some of the sizes indicated in Figure 1 were estimated by this method. The precision of the method can be evaluated by comparing sizes calculated from results of filtration with those obtained by other means. Elford and Andrewes (1932) filtered vaccinia virus and showed that it would just pass through a filter with an average pore diameter of 250 mμ One can estimate, by using the correction factor shown in Table 1, that the diameter of the virus is between 125 and 175 mμ It has since been shown by means of the ultracentrifuge (Elford and Andrewes, 1936; Smadel et al., 1938) and the electron microscope (Green et al, 1942) that the diameter of vaccinia virus is about 225 mμ. The diameter of influenza virus was determined by filtration (Elford et al, 1936) to be between 80 and 120 mμ, whereas by means of the electron microscope the diameter was found to be 82 mμ (Williams, 1953). These data are sufficient to indicate that the method of ultrafiltration can be used to obtain an estimate of the size of a virus but it is apparent that no high degree of precision can be expected However, filtration does have a special use in those cases where the purity of the virus preparation is not great enough to permit other methods to be used

DIFFUSION

One of the important problems confronting those who study viruses is the determination of the size and the shape of the virus particles It has already been shown how ultrafiltration can be used to obtain some idea of size. It is obvious that the electron microscope is admirably adapted to this end. However, until the electron microscope was developed, it was necessary to rely upon indirect methods of [illegible]

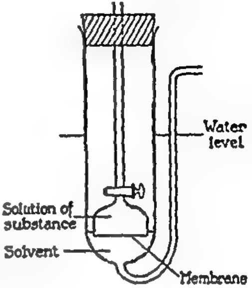
formation which cannot be obtained with the electron microscope. The methods, which include diffusion, ultracentrifugation, viscosity and stream double refraction, stand out for their utility. All of these involve the movement of a particle with respect to the medium in which it is suspended. From the way in which particles move in their surrounding

medium, it is possible to determine something of their size and shape It is the purpose of authors in the following paragraphs to indi- [illegible]

[illegible] particle meets resistance in such movement, and this resistance is proportional to its friction coefficient Thus, in order to interpret diffusion and sedimentation results, it is necessary to understand something about this coefficient

When a particle such as a virus moves through a medium such as water, its motion is opposed by frictional resistance The frictional force, F, acting on the particle is directly proportional to its velocity, v The proportionality constant is called the friction coefficient, f. Therefore, $F = fv$. The size of f depends upon the viscosity of the liquid and upon the size and the shape of the moving particle. According to Stokes' law, $f = 6\pi r\eta$ for a spherical particle where r is the radius and η is the viscosity The viscosity of the liquid can be measured directly Thus one can calculate the radius of a particle from a knowledge of its coefficient of friction If the particle is not spherical, it is more difficult to interpret the meaning of f In this case, the coefficient is an intricate function of the various dimensions of the particle and of the viscosity of the liquid

It is commonly known that if a layer of water is placed very carefully over a concentrated solution of any material the solute molecules will diffuse into the water layer The rate at which a particle diffuses is proportional to the concentration gradient and to a characteristic of the particle known as the diffusion coefficient, D. According to Fick's law, $dS = -DQ\frac{dc}{dx}\,dt$, where dS is the amount of material which will diffuse across an imaginary plane of area, Q, in time, dt, when the concentration gradient is dc/dx Independently, Einstein and Sutherland came to the conclusion that the diffusion coefficient of a particle is inversely proportional to its friction coefficient $D = \frac{RT}{Nf}$, where R is the gas constant, T is the absolute temperature, and N is Avogadro's number Thus, if the



[illegible]

diffusion coefficient of a material can be measured, f can be calculated directly

There are two generally used methods for measuring the diffusion coefficient. The simpler involves placing a solution of the material in a vessel to which a thin, porous membrane has been sealed (Northrop and Anson, 1929) A diagrammatic representation of such a diffusion cup is shown in Figure 4 This filled cell is then placed in contact with pure solvent Through the process of diffusion, the particles on the inside of the cup gradually pass out through the porous membrane into the solvent The diffusion coefficient can be evaluated by measuring the ratio of the concentrations of diffusible material inside the porous cup and outside after a given period of time

A second commonly used method is to place a solution of diffusible material in direct contact with a layer of solvent Several sorts of apparatus have been designed to accomplish this (Lamm, 1937, Neurath, 1942, Kahn and Polson, 1947) After the initial boundary between the diffusing material and the solvent is established, it will gradually become broad because of diffusion, resulting in a gradual change in concentration between the solution

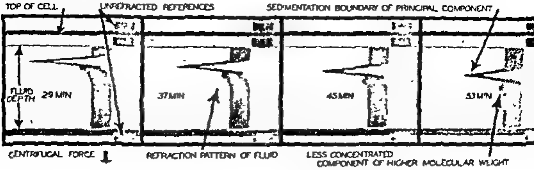


FIG 5. Ultracentrifuge diagram of a 2-component system

and the solvent. This gradual change in concentration can be determined by various optical methods, and from its exact nature it is possible to calculate the diffusion coefficient of the material Neurath and Saum (1938) first attempted the measurement of the diffusion coefficient of tobacco mosaic virus Later, Neurath and Cooper (1940) used it to measure the diffusion coefficient of tomato bushy stunt virus Lauffer (1944a) and Schramm and Bergold (1947) studied the diffusion of tobacco mosaic virus, and Miller and Price (1946) used the method to obtain the diffusion coefficient of Southern bean mosaic virus.

Interpretation of the diffusion coefficient is fairly direct and straightforward in the cases of tomato bushy stunt virus and Southern bean mosaic virus, since these viruses are spherical The diffusion coefficient of bushy stunt virus was found to be 1.15×10^{-7} cm.^{2}/sec (Neurath and Cooper, 1940), and from this a value of 3.49×10^{-7} g/sec. can be calculated for f by means of the Einstein-Sutherland equation By making use of this value and Stokes' law the radius of bushy stunt virus was calculated to be 18.5 mμ. The diffusion coefficient of Southern bean mosaic virus was found to be 1.39×10^{-7} cm.^{2}/sec., corresponding to a radius of 15.3 mμ

SEDIMENTATION

Another method of determining the friction coefficient of a particle is through the study of its sedimentation rate However, unlike diffusion rate, *sedimentation rate does not depend solely upon f.* When a particle moves at uniform velocity through a viscous medium under the influence of a centrifugal or gravitational field, it is subjected to two equal forces, an accelerating force equal to the product of the effective mass and the acceleration of the field, and a force of resistance which is equal to the product of the velocity of the particle and f. Under such conditions one can write the equation $s = \frac{v}{g} = \frac{m_p\left(1 - \frac{d_0}{d}\right)}{f}$, in which v is the velocity of the particle, f is its friction coefficient, g is the acceleration of the field, s is the sedimentation coefficient defined as the rate of sedimentation in a field with unit acceleration, m_p is the mass of the particle, and d and d_0 are the densities of the particle and of the liquid, respectively. This equation states that the sedimentation coefficient of a particle is directly proportional to the mass of the particle corrected for the buoyancy of the liquid and inversely proportional to the coefficient of friction

It is possible to measure the sedimentation coefficient by observing the rate at which the particle moves in a field of known acceleration One merely divides the observed velocity by the acceleration to determine the sedimentation coefficient

In an ultracentrifugation experiment, the virus preparation to be studied, usually at a concentration of from 0.1 to 1 per cent, is placed in a small cell with optically perfect quartz windows in the rotor of the centrifuge. Then the rotor is spun at a known high speed, and if all the particles have exactly the same size, shape and density, all will sediment at exactly the same rate. The particles which were initially at the position nearest the axis of rotation will sediment toward the periphery at the same rate as all the other particles in the solution, but there will be no other par-

ticles to follow them. Thus, they will constitute a moving boundary between a position where there are particles and a position where there is nothing but solvent. The boundary between solvent and solution migrates toward the periphery at the rate of each particle. If the material in the preparation consists of two kinds of homogeneous particles with different sedimentation rates, two boundaries will appear as shown in Figure 5. If a large number of types of particles with slightly different sedimentation rates are present, a single boundary, which becomes blurred with time, will appear. Thus, the centrifuge can be used to determine homogeneity.

There are special optical methods which make it possible to detect a boundary between a solution and its solvent, most of which depend upon the fact that there is a refractive index gradient at such a boundary. By measuring the distance between boundary positions at two known times, it is possible to determine the velocity of migration of the boundary and hence the sedimentation coefficient.

It is relatively simple to interpret the sedimentation coefficient of a spherical particle because both the mass of the particle and the friction coefficient are directly dependent upon the radius. Hence, one can determine the radius of a spherical particle directly from its sedimentation coefficient if the density of the solvent and the density of the particle are known. The density of the dissolved material can be determined in several ways. The simplest method is to calculate it from the weight and the volume of a dry preparation. However, it is quite probable that the density of a biologic particle, such as a protein molecule or a virus particle, is not the same in solution as in the dry state owing to water of hydration.

The ultracentrifuge can be used to determine the density of a virus particle in solution. The equation $s = \dfrac{m_p\left(1 - \dfrac{d_0}{d}\right)}{f}$ shows that the sedimentation coefficient depends upon the density of the solvent. If a particle is suspended in a medium which has exactly the same density as the particle itself, it will not sediment. Therefore, if one can find a

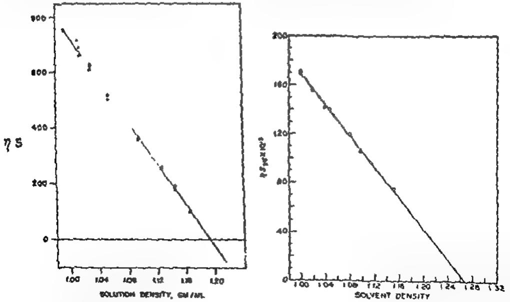

FIG. 6 The sedimentation rates of influenza (*left*) and tobacco-mosaic (*right*) viruses in sucrose solutions of different densities (Lauffer, M. A., and Taylor, N. W., Unpublished results of work on influenza A virus; Schachman, H. K., and Lauffer, M. A., 1949, The hydration size and shape of tobacco-mosaic virus, J. Am. Chem. Soc. 71, 536)

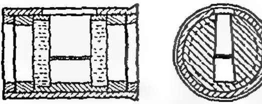

FIG 7 Longitudinal and cross-sectional views of separation cell

solvent in which the virus does not sediment, the virus will have the same density as has the solvent itself Numerous investigators have attempted to determine the density of viruses in solution by sedimenting them in solvents of different densities The method was first used by MacCallum and Oppenheimer, 1922, to estimate the density of vaccinia virus Elford and Andrewes (1936) found that influenza virus had a sedimentation coefficient of zero in a sugar solution with a density of about 1 2 The same method of approach was used by Smadel et al (1938) on vaccinia virus, by Lauffer and Stanley (1944), Sharp and associates (1944a, 1945) and Lauffer and Taylor (1953) on influenza virus, by Schachman and Lauffer (1949) on tobacco mosaic virus, and by Miller and Price (1946) and Lauffer et al. (1952) on Southern bean mosaic virus Schwerdt and Schaffer (1955) obtained a value of 1 56 for the density of poliovirus by the extrapolation of values obtained by sedimentation in mixtures of deuterium oxide-aqueous saline solutions The data obtained with tobacco mosaic virus and influenza virus are shown in Figure 6

The simplest assumption that one can make in interpreting densities so determined is that the sedimenting unit consists of virus plus water of hydration and nothing else. If the dry density of the virus is known, it is possible to calculate the hydration of the virus on the basis of this assumption The question of the interpretation of experiments such as those just described, and others, in terms of hydration, has been discussed by Lauffer and Bendet (1954).

The particles of influenza virus and Southern bean mosaic virus are essentially spherical When the value for the density of influenza virus particles in solution, 1 193 (Lauffer and Taylor, 1951), and the value of the sedimentation coefficient, 722×10^{-13} (Lauffer and Stanley, 1944), are substituted into the equation for the sedimentation of spherical particles, the diameter of the influenza particle in solution can be calculated to be 82 mμ. Values for the sedimentation coefficient and for the density in solution of Southern bean mosaic virus (Lauffer et al., 1952) are $114\ 7 \times 10^{-13}$ and 1.26, respectively. When these values are substituted into the sedimentation formula for spherical particles, a value of 28 mμ is obtained for the diameter

When one attempts to measure and to interpret the sedimentation coefficient of nonspherical particles, considerable difficulty is encountered The measurement is complicated by the fact that the sedimentation coefficient depends upon the concentration. Lauffer (1944b) showed that the reciprocal of the sedimentation coefficient of tobacco mosaic virus is linearly related to the concentration of virus In interpretation, it is necessary to obtain the sedimentation constant at infinite dilution Lauffer showed that this can be done by extrapolation of the data or by applying a correction for the viscosity of the virus solution

The interpretation of sedimentation coefficients is difficult because both f and the mass of a nonspherical particle are complex functions of its dimensions. However, a method has been evolved which makes it possible to determine the size of such particles even though the shape is not known Since both the sedimentation coefficient and the diffusion coefficient of particles are inversely proportional to f, their ratio must be independent of f and depends only upon the mass of the particle corrected for buoyancy These ideas can be summarized by the Svedberg equation: $M = \dfrac{RTs}{D(1 - d_o/d)}$ Thus, from measurements of the sedimentation coefficient, the diffusion coefficient, and the density of a particle in solution, it is possible to calculate its molecular weight regardless of its shape

The ultracentrifuge can also be used to help establish the relationship between particles in a purified preparation and the virus By means of a separation cell (Tiselius et al., 1937), Figure 7, measurements of the sedimentation rate of the entity bearing virus activity can be made The material to be studied is placed in the cell and then is spun at high speed. As

the particles bearing virus activity sediment toward the periphery, they pass through the barrier located in the center of the cell After a certain period of sedimentation, it is possible to stop the centrifuge and to withdraw the contents from the two sides of the barrier for biologic analysis From the relative amounts of biologic activity in the upper and the lower compartments, it is possible to calculate the sedimentation rate of the entity bearing virus activity This figure can be compared with the value obtained for the sedimentation coefficient of the particles If the two coincide, one has strong evidence that the virus activity is actually a property of the isolated particles, and that the particle, therefore, is the virus Evidence of this nature has been obtained for tobacco mosaic virus (Lauffer, 1943a), influenza virus (Lauffer and Miller 1944), Southern bean mosaic (Epstein and Lauffer, 1952) and poliomyelitis virus (Bachrach and Schwerdt, 1954) In the case of tobacco mosaic virus, it was found that the infectious agent sedimented at a rate which was indistinguishable from that of the particle, 15 by 300 $m\mu$ in size In a similar manner the poliomyelitis virus activity was proved to be associated with the 28 $m\mu$ particle

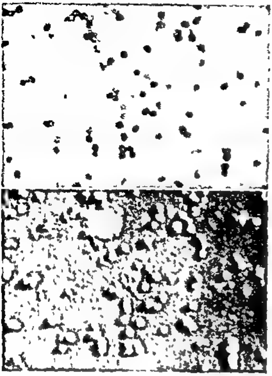
Electron Microscope

Optical Principles One of the most useful aids in the study of viruses is the electron microscope (Wyckoff, 1949, Hall, 1953) With this instrument it has been possible to obtain micrographs of many viruses both in purified form and as they exist in their intracellular environment In order to understand the principles and the operation of the electron microscope it is first necessary to examine some of the fundamentals of electron optics and also to consider the limitations of the light microscope

Although there is no theoretical upper limit to the magnification which can be secured in micrographs taken with ordinary light by the use of glass lenses, there is a distinct limit to the magnification that can be usefully employed In other words, there is a theoretical lower limit to the size of particles that can be distinguished by means of light optics When light is imaged by a lens a certain amount of diffraction occurs at its edge, resulting in phase differences in the light coming from various regions of the lens and forming the image The effect is to render impossible the imaging of a point source as a point image, instead, there is produced in the image a disk-like figure surrounded by faint interference fringes. The disk is called the "circle of confusion" If two point sources of light are very close together their circles of confusion (in the image plane) will overlap, and if the degree of overlap is great, they will be seen as a single source. To be seen as two separated points in the image it is necessary for the point sources to be far enough apart so that their circles of confusion do not overlap by more than one half

Whether or not the two circles of confusion in the image can be distinguished (i e, the two point sources can be resolved) depends upon the distance between the point sources, the wave length, λ, of light, and a property of the lens system called its numerical aperture, or N A The N A of a microscope objective lens is the product of the index of refraction of the material in the space between object and lens *times* the ratio of the lens radius to distance from lens edge to object The distance between two points that can just be resolved is given by the formula $d = \dfrac{0.6\lambda}{N\,A}$ Lenses can be constructed only with numerical apertures of 1 5 or less Therefore, the minimum resolvable distance between two object points is 0.4 λ Since ordinary visible light has a wave length of around 500 $m\mu$, the smallest resolvable distance is about 200 $m\mu$ Most viruses are smaller than this in one or more dimensions and cannot be distinguished in the ordinary light microscope

The electron microscope is in many ways analogous to the light microscope but differs in that electrons, rather than visible light, are the carriers of the radiant energy by which images are formed A source of electrons replaces the conventional light source, and magnets are used in place of glass lenses for the focusing of the electron beam to form real images The electrons from the source are usually accelerated through about 60,000 volts potential and first pass through a magnetic condenser lens that serves to control the degree of electron illumination upon the specimen Since the degree of penetration of electrons of even 60,000 volt potential is quite small, the specimen objects, such as virus particles, must be supported upon a very thin collodion membrane, which in turn is supported on a fine wire mesh When the electrons interact with the material of the specimen some of them are scattered out of the beam that finally forms the image The degree of



Fic
tical
influe
owed preparation that had been treated with $CaCl_2$ to enhance contrast (*Bottom*) The same area of the preparation after being shadowed with chromium (×25,000) (Williams, R C, unpublished)

scattering depends upon the thickness of the specimen object and upon its density Contrast in the final image is thus introduced as a result of the difference in scattering power of various portions of the specimen After passing through the specimen the electron beam passes through a magnetic objective lens and a projector lens to form a real, magnified image of the object. The final image is cast upon a fluorescent screen, where it can be seen by the operator; if photographs are desired, a photographic plate replaces the screen. The interior of the entire instrument is maintained
mole-
scat-

A property of electrons that makes their use profitable for microscopy is that they possess certain wavelike characteristics, so that one may speak of the wave length of an electron beam just as one speaks of the wave length of a light beam At 60,000 volts potential the wave length is only about 0 04 Å. If the N.A. of the objective lens could be made as large as 1.0, the resolving power of the instrument would be well below atomic dimensions In actual practice the N.A must be made much smaller, and as a consequence the best resolutions obtained are in the range of 10-20 Å But even this is some 100 to 200 times better than the resolution afforded by a light microscope and is sufficiently great to permit the smallest of the known viruses to be distinguished with ease.

Limitations. There are two primary disadvantages in the examination of objects such as viruses in the electron microscope. The first arises from the necessity of maintaining a vacuum in the instrument. As a result all specimen objects must be observed in a completely dehydrated condition. A serious consequence, morphologically, of the dehydration is that objects dried directly from aqueous suspension will be seriously flattened and distorted However, this difficulty can be avoided in good part by the use of two technics designed to preserve 3-dimensional morphology. One of these is an adaption for electron microscopy (Williams, 1953) of the well-known process of lyophilization, or freeze-drying The other (Anderson, 1951) is a technic by which the specimen objects are not dried out of water but rather are "dried" from suspension in liquid CO_2 whose temperature is raised above the critical point

The second difficulty encountered in the electron microscopy of objects as small as viruses involves the consideration of image contrast When the particle is extremely small, the electron scattering due to its mass thickness may be only a fraction of that of the surrounding area of the supporting collodion film, and low contrast results A particle as small as a poliomyelitis virus, for example, will appear in a micrograph as only a dark gray object on a background almost as dark.

A method of enhancing the contrast exhibited in the images of small particles and of producing a 3-dimensional impression in the electron micrographs is called shadowing or shadow-casting (Williams and Wyckoff, 1944, 1946). In this technic a very thin film of some heavy metal, such as uranium, is evaporated in vacuo at an oblique angle upon a specimen film that carries the particles, such as viruses, upon its top surface. The evapora-

tion is done simply by heating a small bit of uranium, held in a tungsten filament, to a temperature above its boiling point. Since the atoms of the vaporized metal will travel in straight lines in a vacuum, any projecting particle upon the surface of the specimen film will intercept those atoms that otherwise would have struck the surface behind it. On the film directly behind the virus, then, there will be a region devoid of condensed uranium, while the neighboring film will receive its fair amount. A permanent, metal "shadow" will be produced, and since this region will scatter electrons less than the particle or the surroundings, it will appear black in an electron micrograph negative. Figure 8 shows an example of the increased contrast and detail made visible by shadowing.

Another method of enhancing contrast, but one that has not yet reached a high state of development, is to impregnate the specimen object with a heavy metal that will effectively increase its density (Hall, 1955). This is es- [illegible]

[illegible]

of stains employed in the former art is legion, there are scores of compounds that will react with, or impregnate, biologic materials to form a colored complex. But color, i.e., selective absorption of radiation, does not exist in the formation of electron images. There is only a limited selection of metals dense enough to affect appreciably the scattering of electrons by small objects impregnated with such metals.

Results Obtained With Electron Microscopy. The usefulness of the electron microscope in virus research has expanded rapidly and considerably during the 19 years that have elapsed since the instrument was [illegible]

[illegible]

than the structural features that are actually found on the surface of, and within, virus particles. Also, technics have improved greatly, but it still remains true that the present limitations upon the observation of virus structure are due more to the inadequacies of specimen preparation than to any lack of inherent optical power of the electron microscope. In

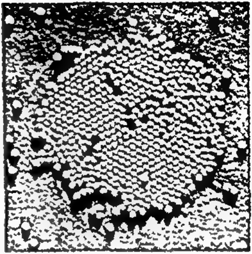


Fig. 9. A small, ordered array of particles of poliomyelitis virus. The virus is so uniform in size that it forms into 2-dimensional crystals when allowed to dry upon the specimen film. (×63,000.) (Schwerdt, C. E., Williams, R. C., Stanley, W. M., Schaffer, F. L., and McClain, M. [redacted] 1954. Morphology of type II poliomyelitis virus (MEF-1) as determined by electron microscopy. Proc. Soc. Exper. Biol. & Med. *86*, 310-312.)

recent years the greatest successes in the use of the instrument have been in the delineation of the structure of purified, intact virus particles and of virus substructures, in the exposition of virus particles in their intracellular environment, and in helping the study of the quantitative relation of virus particles to infection (see Williams, 1957, for a detailed review).

Morphology of Purified, Intact Virus Particles. Many of the viruses responsible for diseases in man, animals, higher plants, insects and bacteria have been photographed with considerable clarity in the electron microscope. Since the intact virus particles usually do not exhibit any discernible interior structure when photographed in unshadowed preparations, most work has been done on shadowed material. As can be seen in Figure 1, both the sizes and the shapes of viruses vary rather greatly. Very generally speaking, the viruses of man and animals are spherical in shape, those of higher plants are rod-shaped or polyhedral, those of insects are shaped like

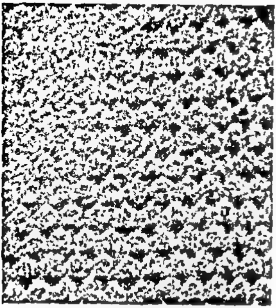

FIG 10 An electronmicrograph of a replica of a plane surface cut through the interior of a single crystal of poliomyelitis virus. (×180,000) (Steere, R L, and Schaffer, F L., 1958, The structure of crystals of purified Mahoney poliovirus, Biochim et biophys acta *28*, [No 2] 245)

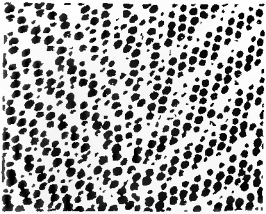

FIG 11 A thin section of a fixed, embedded crystal of the *Tipula paludosa* cytoplasmic virus showing ordered arrays (×20,000) (Williams, R. C., and Smith, K. M., 1957, A crystallizable insect virus, Nature, London *179*, 119-120)

prolate spheroids, while the bacterial viruses are sperm-shaped with polyhedral heads. While surface detail can be seen on some viruses, it is so irregular in arrangement that its significance is an enigma.

Some of the smaller viruses are so uniform in shape and size that they can be caused to aggregate into fairly large, perfect crystals When this occurs it is possible to observe their ordered structure, either by photographing a replica of their surfaces or of a plane cut through their interiors (Steere, 1957) or by photographing a thin section cut from them after fixation and embedding (Williams and Smith, 1957). Figure 9 shows a 2-dimensional array of poliomyelitis virus Figure 10 is an electron micrograph demonstrating the ordered appearance of the poliovirus particles within the interior of a large crystal such as that shown in Figure 3 Figure 11 is a micrograph of a thin section of a crystal of an insect virus

One of the most interesting findings concerning the morphology of viruses has resulted from the application of the freeze-drying and the critical-point technics. This is the demonstration that many viruses are distinctly polyhedral in shape. The heads of all frozen-dried bacterial viruses examined are so shaped, many of the plant viruses are, and even a virus as large as the cytoplasmic virus of the insect *Tipula paludosa* (Frontispiece) is exquisitely polyhedral For the last-named virus it is known that the particle is shaped like an icosahedron, a Platonic solid with 20 faces, each an equilateral triangle The importance of this discovery is its implication that a virus is synthesized from subunits that fit together in an ordered fashion to produce a particle that is in itself at least partially crystalline.

Virus Substructures. In recent years it has been possible to observe some of the smaller structures that go together to make up the intact virus particle. Such structures are obtained by either chemical or physical degradation of the native virus If some sort of chemical or biologic identification of the substructures can be secured, it is possible to obtain an enhanced understanding of the relation of viral structure and function

Work of the nature just outlined has been notably accomplished with the fowl plague virus (Schäfer and Zillig, 1954), the T_2 bacterial virus (Williams and Fraser, 1956), and with tobacco mosaic virus (TMV) (Hart, 1955). It was found that fowl plague virus could be disintegrated by exposure to ether,

following which exposure two components are obtained—a small, ribonucleoprotein particle having certain antigenic properties, and a large, protein particle possessing agglutinating properties. It was proposed that the former particle comes from the interior of the virus, while the latter comes from its outer regions. The T_4 bacterial virus was disrupted by mechanical means and was found to be primarily separable into two identifiable components—the head and the tail. The head, [illegible]

arable into a sheathlike structure, a central core, and a number of fine fibers attached to its distal end. Of particular interest is the discovery that the primary organs of attachment of the whole virus are the tail fibers (Fig. 12), the function of the core is unknown.

Considerable effort has been made to uncover the substructure of TMV. By chemical means it is possible to separate the protein from the ribonucleic acid (RNA) of the virus, and it has been found that the latter is localized co-axially along the virus rod (Fig. 13). The precise geometric fitting of the RNA into the rod is as yet unknown. The protein can be disintegrated into morphologically distinctive units, each of which is a disklike section with a hole in the center, from which the RNA has presumably escaped. The intact virus rod itself has an axial hole, but it is of smaller diameter than the one seen in the disintegrated protein portion. An important finding is that the RNA alone is somewhat infectious, although the protein is not (Fraenkel-Conrat, 1956, Gierer and Schramm, 1956, Fraenkel-Conrat et al., 1957). It is possible to reconstitute the intact virus rod, with almost full return of infectivity, by mixing under proper conditions the previously separated RNA and protein fractions (Fraenkel-Conrat and Wil-

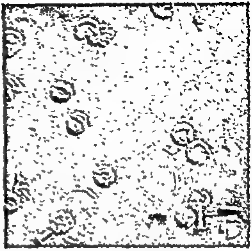

FIG. 12. An electronmicrograph showing some of the substructures of the T2 bacteriophage. Four "ghosts," with tails attached to head membranes, are seen, as well as several head membranes devoid of tails. Also shown are V-shaped fibers that serve as the primary seat of phage attachment. (×48,000.) (Williams, R. C., and Fraser, D., 1956. Structural and functional differentiation in T2 bacteriophage. Virology 2, 289-307.)

FIG. 13. A display of TMV substructures. (*Left*) an intact TMV [illegible]

liams, 1955, Fraenkel-Conrat, 1957). The protein alone can be polymerized into rods (Schramm, 1943). Lauffer et al. (1958) discovered that polymerization involves absorption of heat and must, therefore, be accompanied by an increase in entropy.

Intracellular Viruses. Although information of great value to virologists has been obtained through electron microscopy of purified, intact viruses, and of their substructures, it is evident that a subject of more directly biologic interest is the investigation of viruses in their intracellular environment. Special techniques have been developed to extend the classic methods of histologic preparation to meet the special requirements of electron microscopy. Two requirements of paramount importance are that (1) the fixatives and the stains employed must yield finely granular backgrounds, and (2) the embedding and sectioning methods must produce sections that are extremely thin, on the order of 20 to 50 mμ in thickness. It is found that buffered osmium tetroxide is a satisfactory fixative, with some staining propensities for lipids and proteins. Although its action is not well understood, its practical

velopmental stage. An elongated internal body is surrounded by dense material. These particles are eccentric to the plane of section and therefore appear small. (4) Fowlpox virus at a similar stage. In contrast with vaccinia virus the internal body is separated from the peripheral membrane by a zone of low density. (×130,000) (From Morgan, C., and Rose, H. M., unpublished)

usefulness is unchallenged. Embedding is accomplished in one of the thermo setting plastics, usually butyl methacrylate, while the sectioning is done with specially designed microtomes provided with knives of broken glass, or, recently, of polished diamond

In accord with expectation, the viruses that have proved to be the most amenable to observation are the largest ones or the ones that grow abundantly in the diseased cells and tissues. The viruses well examined in sections are those of the psittacosis-lymphogranuloma group, the pox group, the viruses of influenza, herpes simplex, and the adenovirus group. Without exception these have exhibited a somewhat elaborate but characteristic structure when seen in section within infected cells (Morgan et al, 1954a, 1954b, 1955, 1956) There is a central, electron-dense core, surrounded by one or two concentric membranes Figure 14 and 15 show the appearance of vaccinia virus, fowlpox virus and an adenovirus in intracellular form. The last virus is particularly interesting in that, when within the nucleus, it forms into large well-ordered arrays Influenza gives evidence of proliferating in a somewhat unexpected manner. It is rarely, if ever, found well within the cytoplasm, but rather it appears to be formed as a particle only as it is being extruded from the cell surface

The purpose of looking for viruses in sections of cells is to determine their sites of proliferation and to arrive at some notion as

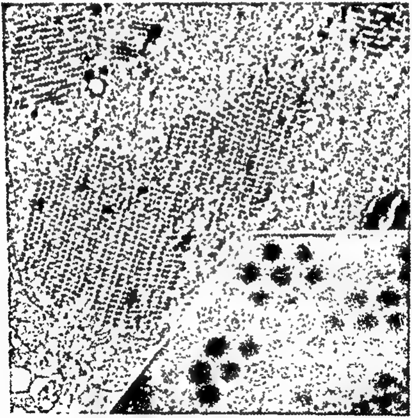

Fig. 15. A thin section [illegible]

to their changes in structure as they are synthesized within the cell It is clear that the former purpose can be satisfied only if there is unequivocal knowledge as to which of the numerous particles seen in sections of cells are viral in nature With the largest viruses, this problem of identification is trivial, but as the smaller viruses are sought, it becomes a difficult, and as yet unsolved, one In order to arrive at conclusions about the changes of virus appearance as the disease progresses within the cells, it is necessary, or at least desirable, to have some measure of time sequence within the infected material With gross tissue involvement there can be no certainty that all cells are infected at the same time, and the questions as to what represents an "early" and what a "late" infection becomes subjective guesswork Recent advances in the use of cultured cells, particularly of single cells, should help to reduce both of the uncertainties discussed.

Quantitative Applications. The electron microscope may be put to considerable use as an instrument for counting the number of virus particles present in a suspension (Backus and Williams, 1950). The method employed is quite simple. A virus preparation is mixed with a suspension of indicator particles, such as spheres of polystyrene latex, whose absolute number concentration is known The mixture is then sprayed upon the specimen films for subsequent electron microscopy. The small spray-drops upon drying form minute drop patterns (Fig 16) that can, and must, be photographed in their entirety. A simple

Fig. 16 Droplet pattern of poliomyelitis virus mixed with a suspension of polystyrene latex indicator particles at a concentration of 3.20×10^{10} particles/ml. The large, opaque spheres are the polystyrene latex particles ($\times$13,500) (From Schwerdt, C. E, unpublished)

counting of the numbers of virus and of indicator particles allows the ratio of their numbers to be determined. This ratio, multiplied by the number concentration of the indicator particles, yields directly the number concentration of the virus particles in suspension. Since this method provides a determination of the number of physical particles present, and biologic titrations can provide a measure of the number of infectious units present in another sample of the same suspension, it is possible to secure an important virologic parameter: the number of physical virus particles necessary for one infectious dose or the specific infectivity. With some bacterial viruses and with vaccinia this number is close to unity (Luria et al., 1951; Overman and Tamm, 1956), with influenza it is probably about 10 (Donald and Isaacs, 1954), while with poliomyelitis it is about 40 (Schwerdt and Fogh, 1957). (See Isaacs, 1957, for a critical review.)

The application of the counting method provides a criterion of viral identification. If an infective preparation, when sprayed and micrographed, is seen to be monodisperse, it is likely that the particles seen are those of the virus. However, if the drop-patterns exhibit two or more distinctive particle types, the question arises as to which particle type is to be associated with the virus. But for each type an apparent specific infectivity can be calculated following biologic titration. The procedure then is to treat the preparation by chemical or physical means such as to change the relative concentrations of the types of particles present. New apparent specific infectivities are obtained, and that particle type for which this parameter remains constant is the most likely candidate for consideration as the virus. This is the method that was employed in the first identification of poliomyelitis virus (Bachrach and Schwerdt, 1954).

X-Ray Diffraction

When a beam of monochromatic light coming from a narrow slit is passed through a diffraction grating and then is focused upon a screen, the image of the light source is found to consist of a series of lines. The central line will be the brightest and will be the principal image of the slit source. Above and below it will be other images of lower intensity. The distance between the successive images depends upon the distance between the diffraction grating and the screen, upon the distance between the lines on the diffraction grating, and upon the wave length of the light. If one knows the wave length of the light and the distance between the grating and the screen, one can calculate the distance between the lines on the grating.

FIG. 17. Longitudinal and cross-sectional representations of arrangement of rod-shaped tobacco-mosaic virus in rodlike crystals. (Lauffer, M. A., and Stanley, W. M., 1939, The physical chemistry of tobacco-mosaic virus protein, *Chem. Rev. 24*, 303-321.)

In a somewhat analogous way, when a narrow x-ray beam is passed through a crystal, the beam is diffracted. The crystal can be considered as a 3-dimensional diffraction grating, because the individual molecules are arranged in a regular 3-dimensional network. The type of diffraction pattern produced with such a 3-dimensional diffraction grating is far more complex than that produced by a 2-dimensional grating consisting of ruled lines on a glass plate. A great number of diffraction spots will be obtained on the photographic plate in the 3-dimensional case. However, the distance between the principal image of the x-ray source and these spots is related to the distance between molecules in the crystal in much the same way as the distance between the lines on a simple diffraction grating is related to the grating spacing. Thus, from an x-ray diffraction pattern of a crystal, one can measure the distance between molecules in that crystal. If it is assumed that the molecules are tightly packed in the crystal, then one can assume that the diameter of the molecule is equal to the shortest distance between molecules. Hence, from x-ray diffraction patterns obtained on crystals one can calculate molecular sizes. The x-ray method has been used by Bernal and Fankuchen (1941) to assess the size of the tomato bushy stunt virus and also to determine the diameter of the tobacco mosaic virus rods. Figure 17 represents diagrammatically the arrangement of rod-shaped tobacco mosaic virus particles in the rodlike crystals of the virus. The particles are arranged with perfect hexagonal sym-

to their changes in structure as they are synthesized within the cell It is clear that the former purpose can be satisfied only if there is unequivocal knowledge as to which of the numerous particles seen in sections of cells are viral in nature With the largest viruses, this problem of identification is trivial, but as the smaller viruses are sought, it becomes a difficult, and as yet unsolved, one. In order to arrive at conclusions about the changes of virus appearance as the disease progresses within the cells, it is necessary, or at least desirable, to have some measure of time sequence within the infected material. With gross tissue involvement there can be no certainty that all cells are infected at the same time, and the questions as to what represents an "early" and what a "late" infection becomes subjective guesswork. Recent advances in the use of cultured cells, particularly of single cells, should help to reduce both of the uncertainties discussed.

of unchanged particles remaining. A result of this sort is conventionally ascribed to a one-hit process.

In spite of the fact that this inactivation is a one-hit phenomenon, the efficiency of inactivation was found to be extremely small. The result was obtained by comparing the total amount of ultraviolet light absorbed by the virus protein at wave length 2537 A with the number of particles inactivated. It was found that something like 25,000 photons are absorbed on the average by each particle which becomes inactivated. Yet, it has been seen that only one of these photons is effective in inactivating the particle.

The action of ionizing radiations on biologic materials, including viruses, has been reviewed by Lea (1947) and by Pollard (1953). The energy from ionizing radiations is absorbed by the irradiated material by the mechanism of ionization. When a tissue is irradiated with x rays or with gamma rays, the photons of radiation collide with atoms and cause ionization by knocking out electrons with very high energies. These electrons or elementary particles of negative electricity speed through the tissue and cause secondary ionizations along their path. Secondary ionization results when an electron is moved out of the orbit of one atom, leaving a positive ion behind, and is captured by another atom, producing a negative ion. The production of each ion pair results in the dissipation of some of the energy of the primary electron, and ultimately all of the energy is dissipated, and the primary electron stops. These ion pairs are produced along tracks, i.e., along the path of the primary ionizing particle. The density of ion production is inversely related to the energy of the primary ionizing electron. Beta rays from radioactive decay or cathode rays are high-speed electrons. These behave in exactly the same manner as the ionizing electrons which result from absorption of x rays or gamma rays. Alpha particles, which are helium nuclei and are produced as a result of radioactive decay, directly induce ion pairs in the tissue. However, alpha particles are very efficient ionizers and therefore produce very dense ionization along a relatively short path. High-speed protons, which can be obtained from a cyclotron, behave somewhat like alpha particles but produce ionization densities intermediate between those of alpha particles and electrons. Neutrons, which can be obtained from the cyclotron, collide with an atom and knock out a proton. This proton in turn behaves in the same way as a proton coming originally from the cyclotron.

It takes energy to produce an ion pair. Ultimately, the excess electrons on the negative members of the ion pairs will find their way back to the electron-deficient orbits of the positive members of the pair, and, when this happens, energy is made available at that spot. This energy leaves the molecule or chemical grouping which contained the ionized atom in a high-energy or excited state, capable of undergoing reaction. If the chemical reaction is in a configuration essential for biologic function, the particle loses its biologic activity.

Irradiation studies on biologic materials, including viruses, are sometimes carried out with the material in solution. In such a case the effect of the radiation can be either direct or indirect, i.e., an ion pair can be produced in the biologic particle itself and directly cause an effect, or it can be produced in the solvent leading to the formation of some substance in the solvent, probably a free radical, which is detrimental to the biologically active material. This indirect effect of radiation can, in principle, be suppressed by irradiating only highly concentrated suspensions or by adding substances like gelatin to the solution for the purpose of absorbing the bulk of the detrimental substances produced. The reality of this distinction between indirect and direct effects as applied to viruses has been demonstrated by x-ray inactivation studies carried out on T_2 bacteriophage by Buzzell and Lauffer (1952) and on tobacco mosaic virus by Buzzell et al. (1956).

When a sample of virus is irradiated in the dry state or when adequate precautions are exercised during the irradiation of solutions, it is usually assumed that the effects observed are the result of direct ionizations within the virus particle. It is customary to interpret the direct action of radiations in terms of the so-called target theory. When a virus is irradiated with a particle which produces dense ion tracks, i.e., tracks along which the ion pairs are so dense that the distance between them is small compared with the size of a virus particle, then the probability that an ionization will be produced within a particular virus particle depends only upon the cross-sectional area of the virus particle and upon

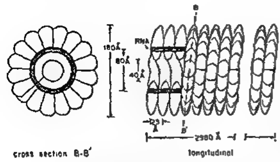

Fig 18 Schematic representation of a tentative structure for tobacco mosaic virus (Stanley, W M, 1956, Virus composition and structure—25 years ago and now, Fed Proc. *15*, 812-818)

metry with respect to cross-section, but with no regularity with respect to length.

The evidence from x-ray analysis as well as that from electron microscopy indicates that the center-to-center separation of the rods of tobacco mosaic virus is 150 Å when the rods are packed in either a 2-dimensional or 3-dimensional array A recent study of the fine structure of the x-ray patterns of the crystalline virus indicates strongly that the exterior of the rods is deeply grooved (Franklin and Klug, 1956). This could account for the observation from radial distribution functions that the total diameter of the rods is as great at 180 Å but that upon close-packing screw-wise intermeshing might occur and thus permit a center-to-center distance of only 150 Å. The localization of the ribonucleic acid in the virus rod has been determined by comparing the radial distribution of electron density of the virus rod with that of the polymerized protein fraction containing no nucleic acid. The difference in the two distributions presumably locates the x-ray scattering electrons in the virus nucleic acid. These results indicate that the nucleic acid, presumably the phosphate groups, is localized some 40 Å from the axis of the rod at a distance about halfway between the axis and the mean outer surfaces (Caspar and Franklin, 1956). There is also evidence from this work that the virus rod has a hole along its axis of radius about 20 Å A schematic representation of a tentative structure for the tobacco mosaic virus molecule is shown in Figure 18. The protein subunits of molecular weight about 17,000 are arranged in the form of a helix with a pitch of 23 Å and with 49 subunits in a length of 69 Å along the rod (Franklin, 1956).

Irradiation

It is well known that viruses can be inactivated or changed in other ways as a result of the effects of various kinds of radiations To understand these effects, it is necessary to differentiate between those radiations which excite atoms and those which ionize atoms Visible and ultraviolet light produce their effect by excitation; alpha, beta, gamma and x-rays, accelerated neutrons, protons and deuterons are ionizing radiations

The effect of nonionizing or exciting radiations on viruses and other biologic materials has been reviewed by McLaren (1949). The effects produced by radiations of this sort represent a special aspect of photochemistry. Experience with photochemical reactions extending over more than a century has led to the formulation of two laws: (1) only light absorbed can cause a reaction; (2) in the primary process one quantum of light is absorbed by each molecule which reacts A molecule which has absorbed a quantum of radiation has a higher energy level than its neighbors. In this high-energy state, it and the group of molecules of which it is a part are likely to undergo chemical change. If the chemical configuration which changes is one of those essential to some vital function, then a biologic change results.

Ultraviolet-irradiation studies have been carried out on many viruses and bacteriophages, e g , equine encephalomyelitis, herpes, influenza, poliomyelitis, vaccinia, rabies, tobacco mosaic and tomato bushy stunt viruses, and *Staphylococcus aureus* and *E. coli* bacteriophages When tobacco mosaic virus was irradiated with ultraviolet light of wave length 2537 Å, it was found that the logarithm of the relative infectivity remaining was inversely proportional to the radiation dose (Oster and McLaren, 1950). This is the kind of result that one gets whenever the rate of the change being measured is directly proportional to the number of individuals remaining unchanged If the absorption of a single photon of radiation is sufficient to cause a virus particle to become inactivated, then the probability of a particular virus particle being hit in a short time interval will be a constant when the radiation intensity is maintained constant The number of virus particles changing in that time will depend only upon the number

of unchanged particles remaining. A result of this sort is conventionally ascribed to a one-hit process.

In spite of the fact that this inactivation is a one-hit phenomenon, the efficiency of inactivation was found to be extremely small. The result was obtained by comparing the total amount of ultraviolet light absorbed by the virus protein at wave length 2537 Å with the number of particles inactivated. It was found that something like 25 000 photons are absorbed on the average by each particle which becomes inactivated. Yet, it has been seen that only one of these photons is effective in inactivating the particle.

The action of ionizing radiations on biologic materials, including viruses, has been reviewed by Lea (1947) and by Pollard (1953). The energy from ionizing radiations is absorbed by the irradiated material by the mechanism of ionization. When a tissue is irradiated with x-rays or with gamma rays, the photons of radiation collide with atoms and cause ionization by knocking out electrons with very high energies. These electrons or elementary particles of negative electricity speed through the tissue and cause secondary ionizations along their path. Secondary ionization results when an electron is moved out of the orbit of one atom, leaving a positive ion behind, and is captured by another atom, producing a negative ion. The production of each ion pair results in the dissipation of some of the energy of the primary electron, and ultimately all of the energy is dissipated and the primary electron stops. These ion pairs are produced along tracks, i.e., along the path of the primary ionizing particle. The density of ion production is inversely related to the energy of the primary ionizing electron. Beta rays from [illegible]

tion of a tentative structure for the tobacco mosaic virus molecule is shown in Figure 18 The protein subunits of molecular weight about 17,000 are arranged in the form of a helix with a pitch of 23 Å and with 49 subunits in a length of 69 Å along the rod (Franklin, 1956).

Irradiation

It is well known that viruses can be inactivated or changed in other ways as a result of the effects of various kinds of radiations To understand these effects, it is necessary to differentiate between those radiations which excite atoms and those which ionize atoms Visible and ultraviolet light produce their effect by excitation; alpha, beta, gamma and x-rays, accelerated neutrons, protons and deuterons are ionizing radiations.

The effect of nonionizing or exciting radiations on viruses and other biologic materials has been reviewed by McLaren (1949). The effects produced by radiations of this sort represent a special aspect of photochemistry. Experience with photochemical reactions extending over more than a century has led to the formulation of two laws: (1) only light absorbed can cause a reaction; (2) in the primary process one quantum of light is absorbed by each molecule which reacts A molecule which has absorbed a quantum of radiation has a higher energy level than its neighbors. In this high-energy state, it and the group of molecules of which it is a part are likely to undergo chemical change. If the chemical configuration which changes is one of those essential to some vital function, then a biologic change results.

Ultraviolet-irradiation studies have been carried out on many viruses and bacteriophages, e g., equine encephalomyelitis, herpes, influenza, poliomyelitis, vaccinia, rabies, tobacco mosaic and tomato bushy stunt viruses, and *Staphylococcus aureus* and *E. coli* bacteriophages. When tobacco mosaic virus was irradiated with ultraviolet light of wave length 2537 Å, it was found that the logarithm of the relative infectivity remaining was inversely proportional to the radiation dose (Oster and McLaren, 1950). This is the kind of result that one gets whenever the rate of the change being measured is directly proportional to the number of individuals remaining unchanged If the absorption of a single photon of radiation is sufficient to cause a virus particle to become inactivated, then the probability of a particular virus particle being hit in a short time interval will be a constant when the radiation intensity is maintained constant The number of virus particles changing in that time will depend only upon the number

of unchanged particles remaining A result of this sort is conventionally ascribed to a one-hit process

In spite of the fact that this inactivation is a one-hit phenomenon, the efficiency of inactivation was found to be extremely small The result was obtained by comparing the total amount of ultraviolet light absorbed by the virus protein at wave length 2537 A with the number of particles inactivated It was found that something like 25,000 photons are absorbed on the average by each particle which becomes inactivated Yet, it has been seen that only one of these photons is effective in inactivating the particle

The action of ionizing radiations on biologic materials, including viruses, has been reviewed by Lea (1947) and by Pollard (1953). The energy from ionizing radiations is absorbed by the irradiated material by the mechanism of ionization When a tissue is irradiated with x-rays or with gamma rays, the photons of radiation collide with atoms and cause ionization by knocking out electrons with very high energies These electrons or elementary particles of negative electricity speed through the tissue and cause secondary ionizations along their path Secondary ionization results when an electron is moved out of the orbit of one atom, leaving a positive ion behind, and is captured by another atom, producing a negative ion The production of each ion pair results in the dissipation of some of the energy of the primary electron, and ultimately all of the energy is dissipated, and the primary electron stops These ion pairs are produced along tracks, i e, along the path of the primary ionizing particle The density of ion production is inversely related to the energy of the primary ionizing electron Beta rays from radioactive decay or cathode rays are high-speed electrons These behave in exactly the same manner as the ionizing electrons which result from absorption of x-rays or gamma rays Alpha particles, which are helium nuclei and are produced as a result of radioactive decay, directly induce ion pairs in the tissue However, alpha particles are very efficient ionizers and therefore produce very dense ionization along a relatively short path High-speed protons, which can be obtained from a cyclotron, behave somewhat like alpha particles but produce ionization densities intermediate between those of alpha particles and electrons Neutrons, which can be obtained from the cyclotron, collide with an atom and knock out a proton. This proton in turn behaves in the same way as a proton coming originally from the cyclotron.

It takes energy to produce an ion pair Ultimately, the excess electrons on the negative members of the ion pairs will find their way back to the electron-deficient orbits of the positive members of the pair, and, when this happens, energy is made available at that spot This energy leaves the molecule or chemical grouping which contained the ionized atom in a high-energy or excited state, capable of undergoing reaction If the chemical reaction is in a configuration essential for biologic function, the particle loses its biologic activity

Irradiation studies on biologic materials, including viruses, are sometimes carried out with the material in solution In such a case the effect of the radiation can be either direct or indirect, i e, an ion pair can be produced in the biologic particle itself and directly cause an effect, or it can be produced in the solvent, leading to the formation of some substance in the solvent, probably a free radical, which is detrimental to the biologically active material This indirect effect of radiation can, in principle, be suppressed by irradiating only highly concentrated suspensions or by adding substances like gelatin to the solution for the purpose of absorbing the bulk of the detrimental substances produced The reality of this distinction between indirect and direct effects as applied to viruses has been demonstrated by x-ray inactivation studies carried out on T_2 bacteriophage by Buzzell and Lauffer (1952) and on tobacco mosaic virus by Buzzell et al (1956)

When a sample of virus is irradiated in the dry state or when adequate precautions are exercised during the irradiation of solutions it is usually assumed that the effects observed are the result of direct ionizations within the virus particle It is customary to interpret the direct action of radiations in terms of the so-called target theory When a virus is irradiated with a particle which produces dense ion tracks, i e., tracks along which the ion pairs are so dense that the distance between them is small compared with the size of a virus particle, then the probability that an ionization will be produced within a particular virus particle depends only upon the cross-sectional area of the virus particle and upon

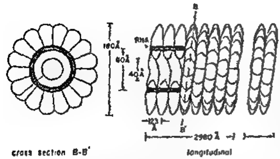

FIG. 18. Schematic representation of a tentative structure for tobacco mosaic virus (Stanley, W. M., 1956, Virus composition and structure—25 years ago and now, Fed Proc 15, 812-818)

metry with respect to cross-section, but with no regularity with respect to length

The evidence from x-ray analysis as well as that from electron microscopy indicates that the center-to-center separation of the rods of tobacco mosaic virus is 150 Å when the rods are packed in either a 2-dimensional or 3-dimensional array A recent study of the fine structure of the x-ray patterns of the crystalline virus indicates strongly that the exterior of the rods is deeply grooved (Franklin and Klug, 1956) This could account for the observation from radial distribution functions that the total diameter of the rods is as great at 180 Å but that upon close-packing screw-wise intermeshing might occur and thus permit a center-to-center distance of only 150 Å The localization of the ribonucleic acid in the virus rod has been determined by comparing the radial distribution of electron density of the virus rod with that of the polymerized protein fraction containing no nucleic acid. The difference in the two distributions presumably locates the x-ray scattering electrons in the virus nucleic acid These results indicate that the nucleic acid, presumably the phosphate groups, is localized some 40 Å from the axis of the rod at a distance about halfway between the axis and

of radius about 20 Å. A schematic representation of a tentative structure for the tobacco mosaic virus molecule is shown in Figure 18. The protein subunits of molecular weight about 17,000 are arranged in the form of a helix with a pitch of 23 Å and with 49 subunits in a length of 69 Å along the rod (Franklin, 1956).

IRRADIATION

It is well known that viruses can be inactivated or changed in other ways as a result of the effects of various kinds of radiations. To understand these effects, it is necessary to differentiate between those radiations which excite atoms and those which ionize atoms. Visible and ultraviolet light produce their effect by excitation, alpha, beta, gamma and x-rays, accelerated neutrons, protons and deuterons are ionizing radiations

The effect of nonionizing or exciting radiations on viruses and other biologic materials has been reviewed by McLaren (1949). The effects produced by radiations of this sort represent a special aspect of photochemistry. Experience with photochemical reactions extending over more than a century has led to the formulation of two laws: (1) only light absorbed can cause a reaction; (2) in the primary process one quantum of light is absorbed by each molecule which reacts A molecule which has absorbed a quantum of radiation has a higher energy level than its neighbors In this high-energy state, it and the group of molecules of which it is a part are likely to undergo chemical change If the chemical configuration which changes is one of those essential to some vital function, then a biologic change results.

Ultraviolet-irradiation studies have been carried out on many viruses and bacteriophages, e.g., equine encephalomyelitis, herpes, influenza, poliomyelitis, vaccinia, rabies, tobacco mosaic and tomato bushy stunt viruses, and *Staphylococcus aureus* and *E. coli* bacteriophages When tobacco mosaic virus was irradiated with ultraviolet light of wave length 2537 Å, it was found that the logarithm of the relative infectivity remaining was inversely proportional to the radiation dose (Oster and McLaren, 1950). This is the kind of result that one gets whenever the rate of the change being measured is directly proportional to the number of individuals remaining unchanged If the absorption of a single photon of radiation is sufficient to cause a virus particle to become inactivated, then the probability of a particular virus particle being hit in a short time interval will be a constant when the radiation intensity is maintained constant. The number of virus particles changing in that time will depend only upon the number

by the method of light-scattering (Oster, 1946; Oster et al., 1947) The method and its biophysical and biochemical applications have been reviewed by Edsall and Dandliker (1951). Particles too small to resolve light might nevertheless scatter it The extent of scattering (therefore, the turbidity) depends upon several factors, among which are the concentration and the molecular weight of the dissolved particles, the refractive indices of solvent and solution and the wave length of light. Thus, from turbidity measurements and measurements of the concentration of the material it is possible to determine the molecular weight For the study of particles much smaller than the wave length of light, the experimental arrangements can be very simple Most of the scattered light will not be transmitted through the solution in its original direction Hence, the ratio of the intensity of light transmitted by the solvent to that of light transmitted by suspension of virus particles is related directly to the turbidity. Transmitted light can be measured in an ordinary laboratory colorimeter Thus, the method of light-scattering may involve only apparatus which is commonly available in clinical laboratories, and it does give satisfactory results for the size of spherical viruses With an apparatus which permits observation of scattering at different angles it is possible to investigate particles having at least one dimension as great as or greater than the wave length of light Oster et al (1947) determined both the molecular weight and the lengths of tobacco virus particles and obtained values in agreement with those determined by other methods The theory of light-scattering parallels that of osmotic pressure For this reason it is possible to investigate the interaction between virus particles or other particles in solution by measuring light-scattering at various concentrations.

Electrophoresis

Viruses, because of their chemical composition, possess carboxyl, amino and other groups capable of ionizing as acids or as bases The dissociation of carboxyl and other acidic groups is suppressed by the addition of strong acids to the medium The addition of strong bases causes the suppression of the ionization of the amino and other basic groups Thus, it can be seen that the relative degree of dissociation of the acidic and the basic groups on the surface of a virus particle and hence its electric charge depends upon the pH of the medium When the protein contains an equal number of dissociated acidic and basic groups, it will have a net electric charge of zero and will be in the iso-electric state

An electric current is carried through a solution of ions by the migration of the ions. Charged macromolecules also migrate in an electric field and thereby help to transport current The velocity of migration of the macromolecules per unit of field strength, generally called the electrophoretic mobility, depends upon the net charge which is a function of pH, upon the electrolyte concentration and the viscosity of the medium, and upon the size and the shape of the charged particles Since the surface chemical composition and the size and the shape of various proteins and viruses differ widely, it is only natural that individual proteins and viruses should have distinctive mobilities in the same solvent Thus, electrophoretic mobility can be used as a means of identifying a protein or a virus and also as a means of separating it from other proteins

Electrophoresis experiments are traditionally carried out in the Tiselius apparatus (Tiselius, 1937, Longsworth 1942), the essential component of which consists of a U-shaped channel of rectangular cross-section connected at each end to a nonpolarizable electrode After a sharp boundary between virus solution and buffer solution is established in each arm of the U-tube, the electrodes are connected to a source of electric potential, and current is sent through the U-tube. If the [illegible] the [illegible] ele[illegible] identical, all will migrate at the same rate Thus, the sharp boundary between solution and solvent will be maintained The U-tube is placed in a thermostatically controlled water bath equipped with a specialized optical system which enables the boundary to be seen and its motion analyzed as with boundaries in the ultracentrifuge

Electrophoresis has been used to purify viruses Price (1946) observed that some preparations of Southern bean mosaic virus contained a dark-brown pigment which could not be removed readily. It was found by Lauffer and Price (1947) that in a 0.02 M

TABLE 2 CORRESPONDENCE BETWEEN X-RAY TARGET AND NUCLEIC ACID VOLUME OF VIRUSES

VIRUS	TARGET VOLUME / TOTAL VOLUME	NUCLEIC ACID VOLUME / TOTAL VOLUME

(Buzzell, A , Trkula, D , and Lauffer, M A , 1956, X-ray studies on tobacco mosaic virus, Arch Biochem & Biophys , *63*, 470-476)

the number of ion tracks per unit of cross-sectional area in the irradiated material This situation would obtain when viruses are irradiated with alpha particles. The fraction of the number of viable virus particles which become inactivated in a given small unit of time then would depend solely upon the dose rate of irradiation and upon the effective cross-sectional area of the virus particle When the dose rate is known, then it is possible in principle to calculate the cross-sectional area from the observed rate of inactivation

When a virus is irradiated with a sparsely ionizing radiation, such as high energy x-rays or gamma rays, then the probability of inactivation depends on the probability of an ionization occurring within the target In this case, fractional biologic response depends on the dose and on the target volume

If inactivation is the result of a single event, i e , either the production of a single ionization within the volume of a single virus particle or the intersection of a particle with one ion track, then the dose-response curve should be a straight line when the logarithm of response is plotted against the dose Many viruses have been irradiated with various kinds of ionizing radiations Representative studies are described by Lea (1947) and by Pollard (1951). In general, the dose-response curves obtained are of the single-hit type Also in the earlier studies, it seemed that the effective particle sizes calculated from such studies are about the same as the sizes of the characteristic particles of the virus as determined by means of electron microscopy and other physical methods

This problem was studied by Epstein (1953), who proposed that the correspondence between nucleic acid volume and target volume for many viruses was so much better than the correspondence between target volume and total volume that it seemed proper to conclude that the real target for the action of x-rays was the nucleic acid Buzzell et al (1956) recalculated some of the data used by Epstein in the light of more refined measurements and of their modification of the theory It can be seen from the results shown in Table 2 that the correspondence between target volume and nucleic acid volume is remarkably good

Lauffer et al. (1956) isolated the nucleic acid from samples of tobacco mosaic virus which had been irradiated with doses up to 8 times the average lethal dose and showed that this material had a much lower intrinsic viscosity than the nucleic acid isolated from unirradiated tobacco mosaic virus This experiment indicates that x-rays may produce their lethal effect by breaking a nucleic acid chain Ginoza and Norman (1957) have shown that the x-ray inactivation dose for isolated TMV nucleic acid is the same as that for the intact TMV.

LIGHT-SCATTERING METHODS

The sizes of the characteristic particles of influenza virus, tomato bushy stunt virus and tobacco mosaic virus have been determined

appear first in the effluent liquid, and others will follow in sequence

An alternative way of operating a column is to cause a large volume of a solution, perhaps containing several substances, to flow through the column and then analyze the effluent liquid on the other end The various constituents of the solution will then be retarded by the amount required to saturate the column The extent of retardation of the appearance of a component depends upon the degree to which it is adsorbed and upon its concentration Thus, if one analyzes the effluent liquid, one will find that it is free of a particular component for a time, and then suddenly this component appears Chromatography experiments carried out in this way are called "frontal analysis" experiments (Tiselius, 1947)

When filter paper is used as the adsorbent, the usual technic is to place a small streak of a solution containing several components near the bottom of a strip of filter paper The pure solvent is allowed to rise by capillary action through the strip Then the components in the streak are separated into bands along the paper, the position of the band depending upon how strongly a particular substance is adsorbed At the end of the experiment, the bands can be located by the use of dyes, by ultraviolet light or, if the substances happen to be colored, by ordinary visual observation The paper can be cut into pieces, and in this way the components of any one band can be recovered for analysis

Paper chromatography has been applied to the study of viruses Gray (1952) studied tobacco mosaic virus, and Goldstein (1956) Southern bean mosaic virus by this technic

Numerous studies have been carried out using ion exchange resins for the purification of viruses Matheka and Armbruster (1956) and other workers used a strongly basic resin for the purification of influenza virus, and Shainoff and Lauffer (1956) used such a resin for the purification of Southern bean mosaic virus Bradley and Rich (1955) and Commoner et al (1956) used an anion exchange cellulose preparation for the separation of nucleic acid and protein degradation products of tobacco mosaic virus Tiselius (1954) carried out chromatography of tobacco mosaic virus on calcium phosphate

Shainoff and Lauffer (1957) used frontal analysis chromatography on a strongly basic anion exchange resin for the purpose of identifying the infectious entity with the characteristic particle of Southern bean mosaic virus The retention of the infectious entity was the same as that of the nucleoprotein under all of the conditions studied Because of the sharpness of the boundaries of the fronts, the experimental error in the retention volume of the infectious entity was not greatly influenced by the accuracy of the bio-assay. Thus, evidence for the identity of the infectious entity with the characteristic particle was obtained

Chemistry

Chemical Analysis Elementary chemical analyses have been made on purified preparations of several viruses and several strains of the same virus Unfortunately, such data are not very informative, since about all that can be concluded is that the data are compatible with what might be expected for the general class of nucleoproteins The plant viruses appear to be the least complex chemically, for all which have been purified have been found to be simple nucleoproteins The amount of nucleic acid has been found to vary from about 6 per cent in the case of tobacco mosaic virus to about 35 per cent in the case of tobacco ring spot and turnip yellow mosaic viruses (Bawden and Pirie, 1937, Stanley, 1939, Stanley and Loring, 1939, Ross and Stanley, 1939, Steere, 1956, Cosentino et al, 1956) The Shope rabbit papilloma virus appears to contain about 1 5 per cent of lipid in addition to nucleoprotein (Taylor et al, 1942) Influenza virus has been found to contain, in addition to nucleoprotein, a polysaccharide composed of mannose, galactose, fucose and glucosamine units, and lipid (Ada and Gottschalk, 1956, Knight, 1947a, Frommhagen et al, 1958) Equine encephalomyelitis virus was found to contain large amounts of lipid in the form of phospholipid, cholesterol and neutral fat (Beard, 1945) The viruses which have been purified and studied have been found to consist of various combinations of nucleic acid and protein with lipid, extranucleic acid carbohydrate or certain other components which are present in some instances Thus far, only pentose nucleic acid has been found in the plant viruses, while either pentose nucleic acid or deoxypentose

TABLE 3

Southern bean mosaic	5 9	MacDonald, Price and Lauffer, 1949

phosphate buffer at pH 7, this pigment migrated more rapidly in electrophoresis than did the Southern bean mosaic virus, thus allowing a separation to be made Schramm et al (1955) used electrophoresis to purify the protein fraction isolated from tobacco mosaic virus

The electrophoresis apparatus can also be used for determining the electrophoretic homogeneity of a virus preparation by observing whether or not the boundaries are single or multiple, or whether they are sharp or diffuse, as in the analysis of boundaries in the ultracentrifuge Electrophoresis experiments may also be carried out on filter paper A virus solution is placed on a strip of filter paper saturated with buffer, and the strip is allowed to make contact with electrodes at the two ends. When an electric current is passed through the strip, the protein material migrates electrophoretically at a characteristic rate Gray (1952) carried out such studies on tobacco mosaic virus, cucumber mosaic virus and tomato spotted wilt virus. Zaitlin (1956) used filter paper electrophoresis to separate strains of tobacco mosaic virus

One of the characteristic physical constants by which a virus can be identified is its isoelectric point. At the iso-electric point, it will not migrate either to the positive or the negative electrode in an electrophoresis apparatus. The iso-electric point can be determined by measuring the electrophoretic mobility in buffers with different pH values and establishing the pH at which there is no migration To- phoretically homogeneous. Their isoelectric points have the values indicated in Table 3 The isoelectric point may vary with the concentration of the buffer, as was shown by Hartman and Lauffer (1953) for Southern bean mosaic virus, Different strains of the same virus may have different iso-electric points, as was shown for tobacco mosaic virus by Oster (1951), by Gordon and Price (1953), and by Ginoza and Atkinson (1955)

Electrophoresis can also be used to help establish the identity between a particle and the infectious entity in a manner analogous to the procedure used with the centrifuge. Hartman and Lauffer (1953) found that over a large pH range the electrophoretic mobility of the infectious entity in a Southern bean mosaic virus preparation coincided with that of the characteristic particle Miller et al. (1944) found that the red blood cell precipitating activity of influenza virus migrated in an electric field with the same rate as the particles commonly regarded as the influenza virus particle

CHROMATOGRAPHY

It has been mentioned earlier that viruses can be adsorbed to and eluted from various finely divided solid materials. When the adsorption and elution process is carried out by the method of moving the material through a long column packed with the adsorbent or along a strip of filter paper, it is given the name, "chromatography"

There are several ways of carrying out chromatographic operations One is to place on a tightly packed column of adsorbent a small amount of a solution containing several components Then solvent is forced through the column, and this causes the original band of solutes to move in the direction of flow The less strongly adsorbed substances move more rapidly than the more strongly adsorbed After a time, the components of the solution are separated into distinct bands distributed along the column. If the components happen to be colored, these bands can be seen directly Frequently, a band will be found to contain a single pure substance One way of recovering pure material is to divide the column into sections corresponding to the various bands Another way is to allow solvent to continue flowing; the most rapidly moving band will come to the end of the column and

strains of tobacco mosaic virus (Reddi, 1957). The polynucleotide chains of tobacco mosaic virus nucleic acid seem to be terminated by 3'-phosphomonoester groups (Markham et al., 1954; Reddi and Knight, 1957). Because the methods that were employed formerly to secure the nucleic acid components of viruses for chemical studies were not designed to retain biologic activity, it is probable that some of these preparations were altered considerably. Cohen and Stanley (1942) found that the nucleic acid obtained by alkali treatment of tobacco mosaic virus was only slightly viscous and possessed a molecular weight of about 15,000, whereas the nucleic acid obtained by heat treatment was very viscous, spontaneously birefringent and possessed a molecular weight of about 300,000. Fraenkel-Conrat and Singer (1958) have studied the effects of different solvents, metals and chelating agents on the biologic activity of nucleic acid preparations obtained by treatment of tobacco mosaic virus with either sodium dodecyl sulfate or phenol.

Fraenkel-Conrat and Williams (1955) found that tobacco mosaic virus nucleic acid would enter into combination with the viral protein subunits to form rods 15 $m\mu$ [redacted] diameter, many with lengths and specific viral activity similar to those of the intact virus. The fact that the virus activity per unit weight of nucleic acid is increased from 20-fold to 100-fold when the nucleic acid is incorporated in the protein, and that the nucleoprotein has a stability much greater than that of the free nucleic acid indicates that the protein is of importance in the infectious process. Hart and Smith (1956) have found that different artificial and natural ribonucleotide polymers would interact with tobacco mosaic virus protein to form nucleoprotein rods somewhat similar to those of tobacco mosaic virus but possessing no virus activity. Fraenkel-Conrat and Singer (1957) have studied the reconstitution of virus particles from protein and nucleic acid preparations of different virus strains and have found that the nature of the disease and the progeny produced by such mixed viruses appeared to be governed by the nucleic acid component. Since mixtures of nucleic acids may be packaged together, this may provide a new approach to the study of genetic recombination in viruses. The discovery that tobacco mosaic virus nucleic acid possesses virus activity by itself and that the virus nucleoprotein can be reconstituted from protein and nucleic acid subunits has opened up many new research opportunities of great potential in virus research.

Chemical Modification. In early studies on the inactivation of tobacco mosaic virus, [redacted] was found that treatment with hydrogen peroxide, formaldehyde or nitrous acid yielded inactive virus which still retained certain characteristic chemical and serologic properties (Stanley, 1936). The reaction with formaldehyde was studied in some detail by Ross and Stanley (1938), who found that the inactiva-
[illegible]

formaldehyde was dialyzed [redacted] pH 3, a 10-fold greater activity was obtained following dialysis than before. This was interpreted to mean that the virus was reactivated by dialysis. This difference was also found to be accompanied by differences in amino nitrogen and in the groups that react with Folin's reagent. Kassanis and Kleczkowski (1944) reported that they were unable to secure reactivation of formolized virus, but the experiments of Ross and Stanley have been repeated, and the results confirmed in another laboratory (Fischer and Lauffer, 1949a). Heicken and Spicher (1956) found that formaldehyde inactivated T_3 bacteriophage preparations could be largely reactivated by treatment with amino acids such as asparagin, tryptophan or histidine.

Considerable progress has been made toward understanding the way in which tobacco mosaic virus is inactivated by formaldehyde as a result of studies of the kinetics of the reaction. Ross and Stanley (1938) showed that the inactivation of tobacco mosaic virus by formaldehyde is a reaction of the first order over most of the course of inactivation, and this was confirmed by Fischer and Lauffer (1949b). A first-order reaction is one in which the amount of primary reactant remaining unchanged decreases exponentially with time. This type of reaction implies that the number of particles changing in a very short interval of time is directly proportional to the number remaining unchanged. When one plots

nucleic acid or both have been reported to be present in animal viruses.

Although all strains of tobacco mosaic virus were found to contain the same amount of nucleic acid, as indicated by phosphorus analyses, they possessed different chemical properties (Stanley, 1937a, 1943). The properties of different preparations of tobacco mosaic virus obtained at different times of the year and even from different kinds of hosts were found to be identical by all tests applied (Stanley and Loring, 1936, Stanley, 1938b, Gaw and Stanley, 1947) The first studies on the amino acid composition of different strains of tobacco mosaic virus were made by isolation and colorimetric methods but later were supplemented by microbiologic and chromatographic methods (Ross and Stanley, 1939; Ross, 1941b, 1942, Knight, 1942, 1947b; Black and Knight, 1953, Ramachandran, 1957) Differences in the composition of the 8 strains were found to involve 16 of the 19 amino acids that were determined In some cases, a strain is characterized by changes in the amount of one or more amino acids, by the introduction of a new amino acid or by the elimination of an amino acid On the other hand, deFremery and Knight (1955) in a study of purified preparations of 3 strains of tomato bushy stunt virus found no decisive differences in amino acid composition Despite the profound differences in composition that have been found in strains of tobacco mosaic virus, the particles of these strains appear to have the same size and shape.

At the present time attention is being turned toward the determination of amino acid sequences in the proteins of tobacco mosaic virus strains Preliminary results indicate that differences in sequence occur in different strains of this virus (Niu and Fraenkel-Conrat, 1955, Knight, 1956, Narita, 1957). Niu et al (1958) have found the C-terminal residues of tomato bushy stunt virus, potato X virus and the cucumber viruses 3 and 4 to be leucine, proline and alanine, respectively. No free amino terminal groups were found

Amino acid analyses have also been made on highly purified preparations of the PR8 strain of influenza A virus, the Lee strain of influenza B virus (Knight, 1947b), and the Shope rabbit papilloma virus (Knight, 1950) Although purified tobacco mosaic virus and its strains were found to be unrelated immunochemically to the proteins of the normal hosts used to produce the viruses, the influenza viruses were found to be related immunochemically to materials present in the hosts (Chester, 1935, Knight, 1946a, b, Gaw and Stanley, 1947, Malkiel, 1947).

The significance of chemical differences in the protein components of viruses was altered somewhat with the very important discovery by Fraenkel-Conrat (1956), and independently and almost simultaneously by Gierer and Schramm (1956), that nucleic acid preparations possessing virus activity could be obtained by degradation of the tobacco mosaic virus nucleoprotein It now appears that the nucleic acid alone carries the biochemical message which results in the production in an appropriate host not only of a specific nucleic acid but also of a specific protein which eventually serves as a protective coat for the biologically active nucleic acid. This conclusion is consistent with earlier work which indicated that deoxyribonucleic acids carried the transforming activity of the pneumococcus (Avery et al, 1944) and was also responsible for phage replication activity (Hershey and Chase, 1952) It is obvious that great emphasis must now be placed on studies of viral nucleic acids

The nucleic acid component of tobacco mosaic virus has been studied by Loring (1939) and by Schwerdt and Loring (1947), and it was concluded that at least 3 of the component nucleotides were identical with those of yeast nucleic acid Knight (1952) studied the molar proportions of the bases in strains of tobacco mosaic virus and found no differences. However, the immunologically related cucumber 3 and 4 viruses were found to contain decidedly less adenine and more uracil Differences in base ratios were also found in the cases of tomato bushy stunt, Southern bean mosaic and potato X viruses (Markham and Smith, 1951; Dorner and Knight, 1953). Ribonuclease treatment has yielded no evidence for differences in the composition of the ribonuclease-resistant cores of nucleic acids from strains of tobacco mosaic virus (Reddi and Knight, 1956), although evidence has been obtained that the intramolecular distribution of pyrimidine nucleotides in the masked strain differs from those of other

viruses when treated in a similar manner with carboxypeptidase.

The use of stable and radioactive isotopes in research work on viruses will doubtless yield important results. Stanley (1942b) and Schramm et al (1942) prepared tobacco mosaic virus containing radioactive phosphorus Although the phosphorus did not dissociate from the virus in vitro, it was found to be dissociable following inoculation into plant cells; hence, the virus containing radioactive phosphorus did not prove to be useful in connection with experiments designed to yield information concerning the mode of virus reproduction However, it does appear likely that the use of tracer technics may provide an answer to the important question as to whether or not the substance of virus used as inoculum appears in the progeny or newly formed virus particles Important advances have already been made in this direction in studies on the reproduction of bacteriophages using radiophosphorus, radiosulfur, radiocarbon and heavy nitrogen Hershey et al (1951) found that phage preparations containing a high specific activity of incorporated radiophosphorus are inactivated progressively by the decay of their radioactive atoms, and Stent (1955) subsequently observed that at the outset of their intracellular reproduction such P^{32}-labeled phages become refractory to inactivation by radioactive decay One of the most significant isotope experiments was carried out by Hershey and Chase (1952) who demonstrated that it is only the viral phosphorus (i e , DNA) and not the viral sulfur (i e , protein) which penetrates into the interior of the infected bacterium Putnam and Kozloff (1950) discovered that about half of the DNA so introduced into the host cell by the parent virus is ultimately transferred to the progeny virus particles In this process of transfer from parent to progeny, the phosphorus atoms of the parental DNA become distributed over several progeny particles, as could be shown by means of direct autoradiographic measurements (Levinthal, 1956) or by the lethal effects produced by the transferred P^{32} atoms (Stent and Jerne, 1955)

Dunn and Smith (1954) and Litman and Pardee (1956) have studied the incorporation of 5-bromouracil into bacteriophages The latter workers found that 5-bromouracil has a powerful mutagenic effect, presumably because of a disturbance of deoxyribonucleic acid metabolism. The percentage of mutants is about 15, the highest as yet recorded.

Kinetics of Disintegration

It has been found that tobacco mosaic virus is disintegrated very much more rapidly at extremely high pressures than at ordinary pressures (Lauffer and Dow, 1941). That is, even though the virus is perfectly stable at 30° C. at atmospheric pressure, it will disintegrate if it is subjected to a pressure of from 5,000 to 10,000 atmospheres at 30° C. The course of the disintegration at high pressures has been shown to be of the first order. The effect of high pressures on the disintegration of tobacco mosaic virus can be understood on the basis of the assumption that the partially denatured virus particles occupy slightly less volume than the normal virus particles If this is so, then one would expect the application of high pressures to shift the equilibrium in such a way as to increase the proportion of particles in the partially denatured state Thus, the reaction rate would be speeded up More recently, Johnson et al (1948) showed that at pressures around 500 atmospheres the denaturation of tobacco mosaic virus protein was less rapid than at atmospheric pressure This result indicates that the denaturation processes at 500 and at 7,500 atmospheres are not the same

The disintegration of tobacco mosaic virus by urea presents some very interesting features (Stanley and Lauffer, 1939, Lauffer, 1943b, Lauffer and Stanley, 1943) When the virus is placed in a strong urea solution, it gradually disintegrates This reaction has been shown to be of the first order The specific reaction rate was found to vary with the temperature in an unexpected and unusual manner The disintegration of tobacco mosaic virus in urea proceeds slowly at room temperature, but the rate is increased when the temperature is raised above room temperature and also when it is lowered below room temperature. Other viruses have been shown to behave in the same manner (Bawden and Pirie, 1940) This very unexpected behavior can be explained on the basis of the assumption that the virus reacts with urea to form a complex compound which then undergoes disintegration By making the postulate that at least two different kinds of complexes can

the logarithm of the amount remaining against time, the slope of the resulting straight line is called "the specific reaction rate"

It is commonly observed that, when the natural logarithm of the specific reaction rate for many chemical reactions is plotted against the reciprocal of the absolute temperature, the data fit a straight line From the slope of this straight line, one can evaluate the energy of activation In studies on the inactivation of tobacco mosaic virus by formaldehyde at several pH values Cartwright et al. (1956) found energies of activation of approximately 19,500 cal/mole. This value is approximately that which one obtains with ordinary chemical reactions involving a single chemical bond and *would indicate that the rate-determining step* involves a single chemical bond. The same conclusion is indicated by the fact that the rate of inactivation is directly proportional to the first power of formaldehyde concentration *This is not to say that only one formal*dehyde molecule reacts with a virus particle Indeed, there are undoubtedly thousands of formaldehyde molecules combined with each virus particle after the reaction is completed. It means only that, of the large number of formaldehyde molecules which do react, a single one is responsible for the loss of biologic activity Fraenkel-Conrat (1954) found that formaldehyde can react with the nucleic acid of the intact tobacco mosaic virus, and Staehelin (1957) in studies with the separated nucleic acid found experimentally that only about 3 formaldehyde molecules need to be bound to render the nucleic acid inactive It is not unreasonable to conclude that re*action of a single formaldehyde molecule* at a single site on the nucleic acid of the virus may cause inactivation

The studies of Cartwright et al (1956) show that the rate of the inactivation is independent of pH over the range pH 4-8. This can be interpreted to mean that the critical group for inactivation in the presence of formaldehyde is one which does not ionize in this pH range Possibilities are the OH group on the ribose and the NH_2 of the purine and pyrimidine residues

Anson and Stanley (1941) reported that the sulfhydryl groups of tobacco mosaic virus could be oxidized with iodine without changing the specific virus activity, but that the inoculation of this oxidized virus in Turkish tobacco plants resulted in the production of ordinary tobacco mosaic virus Fraenkel-Conrat (1955) found that iodine transforms the sulfhydryl of tobacco mosaic virus into a stable sulfenyl iodide group which becomes unstable upon denaturation of the virus Carpenter and associates (1948) treated tobacco mosaic virus with benzyl or n-butyl β-chloroethyl sulfide and found that the vesicant residues were attached to both the nucleic acid and the protein moieties of the virus and that the vesicant-protein linkage was more labile to alkali than was the vesicant-nucleic acid linkage. Miller and Stanley (1941, 1942) found that chemical derivatives of tobacco mosaic virus could be obtained by treatment with ketene, phenyl isocyanate, carbobenzoxy chloride, p-chlorobenzoyl chloride and benzenesulfonyl chloride Knight (1951) prepared dinitrophenyl derivatives of tobacco mosaic virus and Fraenkel-Conrat (1953) was able *to introduce an amino acid, namely, leucine,* into the virus structure. It is of interest that the coverage of functional groups which can be accomplished without change in specific virus activity, as measured on leaves of *Nicotiana glutinosa,* corresponds to about 3,000 amino groups and from 2,000 to 4,000 phenolic groups per molecule of tobacco mosaic virus In the light of the recent work with infectious nucleic acid it is not surprising that the disease caused by these chemical derivatives in Turkish tobacco plants was found to be indistinguishable from the ordinary tobacco mosaic disease, and that the virus isolated from such plants was found to be indistinguishable from ordinary tobacco mosaic virus.

Harris and Knight (1955) studied the action of carboxypeptidase on tobacco mosaic virus and found that about 2,900 threonine residues and only theronine were released per *molecule of virus Further, it was found* that the biologic properties and the size, the shape and the density of the treated virus were the same as those of the original virus. Knight (1955) also found that the same amount of threonine and only threonine was split from each of 13 strains of tobacco mosaic virus on treatment with carboxypeptidase In contrast, smaller quantities of several amino acids were split from potato X, Southern bean mosaic, tomato bushy stunt and tobacco ring spot

be formed with urea, one can explain the unusual dependence of reaction rate upon temperature

Rather extensive studies on the kinetics of the destruction of infectivity of tobacco mosaic virus and of other plant viruses were carried out by Price (1940) In general, it was found that these inactivations follow the course of a first-order reaction The kinetics of the loss of red blood cell agglutinating activity and of infectivity of the PR8 strain of influenza A virus has been studied by Lauffer and associates (Lauffer and Carnelly, 1945, Lauffer and Wheatley, 1951, Lauffer et al, 1948, Scott and Lauffer, 1946a, b). Studies of this sort are of importance to virologists because they shed light upon the inactivation of viruses at high temperatures During much of the early work, a given virus was characterized by its inactivation temperature or its thermal death point This was defined as the temperature at which a virus would be inactivated in some arbitrary time It is now realized that the thermal inactivation of a virus is merely one aspect of the broader problem of the denaturation or disintegration of virus proteins Inactivation is a reaction which takes place over a wide range of temperatures. However, the reaction has the property of changing velocity greatly for small temperature changes Thus, a change of temperature of only a few degrees can cause the reaction velocity to change from an imperceptibly low value to one so high that virtually all of the activity is destroyed in a short period of time Hence, one can obtain an apparent inactivation temperature. These inactivation temperatures or thermal death points were used as characteristics to describe the nature of a particular virus Much more useful information can be obtained from data describing the way in which the rate of the inactivation varies with temperature and with other conditions.

Biochemistry of the Virus-Infected Cell

INTRODUCTION

A certain amount of biochemical information relevant to the mechanisms of virus multiplication has been available for many years However, the biochemistry of virus-infected cells as such has been studied for only a decade All earlier examinations of the biochemical effects of virus infection employed virus-infected tissue of higher animals and plants, and therefore the effects observed were not only a composite of normal behavior and the behavior of infected cells but also included the secondary effects which may occur as a result of the interaction of normal and infected cells in a milieu of the products of destroyed cells Secondary inflammatory changes were also an additional potential complicating factor in infected animal systems In such a situation the definition of the time relations of the stages of multiplication and of the primary effects of infection upon host cells in biochemical terms is almost impossible to achieve

It is instructive in this connection to examine the discussion which arose in the period of 1942 to 1946 between two capable groups of biochemists around the apparent metabolic effects of infection by poliomyelitis virus Since the energy sources of brain are predominantly derived from carbohydrate metabolism, and a number of the relevant enzyme reactions, such as those involved in anaerobic glycolysis, are studied readily, it seemed reasonable to determine if the capacity for anaerobic glycolysis in homogenates of brains of mice infected by poliomyelitis virus was altered significantly It was first reported that such homogenates showed a slightly inhibited (about 15%) anaerobic glycolysis (Racker and Kabat, 1942), and it was concluded that the virus may act by interfering with this metabolic activity of the nerve cell. Another group tried without success to repeat these results (Utter et al, 1945, Wood, 1944) Indeed, the latter worker concluded that since only a small portion of the brain cells was visibly damaged by infection, it was not likely that one could hope to reveal the potentially small difference in enzyme concentration in a homogenate of whole infected brain, even if the methods available for estimating enzyme activity and concentration were satisfactory Continuing investigation into this problem by this approach has revealed only a maze of complexities of experimental detail and difficulties in interpretation (Racker, 1954)

The problem of describing the biochemistry of normal tissue is difficult enough at best Modern biochemistry has had many successes in the isolation and the characterization of cell fragments and components, including such functional units as enzymes, but the discipline has had relatively few successes as yet in interpreting the behavior of intact functioning cells and tissues in biochemical terms. Nevertheless, in addition to the tasks of dissecting cellular structures and the intermolec-

ular reactions which are at the foundation of catalytic activity at a molecular level, the problem of interpreting the biologic activities of intact cells and tissues in terms of the organization and the activities of their molecular components is now recognized to be a major task of biochemistry. Therefore, we have entered consciously and determinedly into the area of cellular biochemistry, a branch of biochemistry well suited to the problems of virus disease, which for our present purposes may be considered primarily as cellular disease

In the light of these past experiences then, it can be seen that an essential prerequisite for the analysis of the biochemistry of viral infection had to involve the development of a methodology in which quantitative biology was the keystone How many host cells are we dealing with and what is their nutritional history? Are they all of one kind, i e, are they derived from a single clone? What proportion of the cells is infected, and when did this occur? When is virus released, and is this accompanied by cell destruction? These are the kinds of biologic information which we must have before we can obtain the most significant biochemical data.

Such controlled biologic systems may be afforded most readily (1) if relatively uniform populations of host cells derived from single cell lines may be grown separately in defined media and estimated as discrete units, (2) if purified virus preparations can be obtained, consisting predominantly of accurately and easily assayable infectious units, and (3) if infection can be established by a simple process of mixing cell and virus populations in such a way that the distribution of virus particles per cell may be calculated readily from the Poisson equation and confirmed by the differential estimation of free virus and infected cells.

The important conditions listed above for a controlled biologic system were first met for bacteria and certain virulent bacteriophages As a result of the pioneering investigations described in Chapter 7, the phenomenon of an infectious cycle was clearly demonstrated and analyzed

It was found that bacteria could be grown as separate cells under defined conditions and controllably infected with these phages The intensive study of a group of 7 phages, called T_1 through T_7, infecting the bacterium, *Escherichia coli*, was begun in the early 1940's by a small group of research workers who saw in this biologic system the opportunities for just such a rigorous quantitative biology which might permit a detailed analysis of the phenomena of virus multiplication and of mechanisms of viral inheritance. Infected cells remained intact for reproducible intervals, depending on the conditions of media, temperature, aerobiosis, etc After a period of virus multiplication the cells lysed, liberating many more virus particles than had been used originally to establish infection Electron microscopy revealed the characteristic morphology of the infecting virus particles and of the derived progeny at lysis (Luria et al, 1943). Purified concentrates of phage were obtained from lysates by differential centrifugation (Anderson, 1945), as described earlier by Schlesinger (1934, 1936) The chemical analysis of concentrates of the T_2 bacteriophage was begun (Hook et al, 1946, Cohen and Anderson, 1946) as an essential preliminary to the exploration of the metabolism of virus-infected cells, since it seemed reasonable to suppose that a knowledge of virus constituents might suggest the areas of metabolism in which the infected cell might be studied most profitably. The continuing analysis of this and related viruses has produced the most unexpected results—results which have been correlated with important biologic properties of the T_2 virus, and the virulence of the infections it produces The study of the multiplication of the T-even bacteriophages, i e., the T_2, T_4 and T_6 viruses, has been pursued in great depth, and it is now evident to most virologists that the major remaining problems with these systems primarily involve questions of the molecular architecture of virus structures and the interactions of these structures at molecular levels with a variety of bacterial components whose nature must also be understood at molecular levels Major biologic problems in these systems have been reduced to chemical and physical problems The chemists and the physicists, in taking advantage of the biologic tool which these systems make available, will not only obtain information relevant to mechanisms of virus multiplication but also will learn of hereditary units and the storage

of genetic information in molecular structure, of the transmission of genetic information and the duplication of structure, of the relation of genetic duplication to the development of cellular physiology and cellular pathology; and of many other basic problems of cellular biology. The fruits of investigation in this field have already provided an overwhelming demonstration of the importance of a sound quantitative methodology in the approach to biologic and biochemical problems

However, although it is clear that the biochemical study of bacteria infected by bacterial viruses is well developed, it must be noted that a comparable study of the biochemistry of animal viruses and their multiplication has barely begun It is only in the last 5 years that the task of analyzing the biology of animal virus multiplication at the cellular level has been assumed in a manner comparable with the approach used with the basteriophages The largest impetus for this development came from the demonstrations that, as in the assay of bacterial viruses, some animal viruses will produce plaques on monolayer tissue cultures (Dulbecco, 1952) and that these viruses will also grow in cell suspensions and in single cells (Dulbecco and Vogt, 1953) The first of these findings suggested that animal viruses might be assayed as accurately and as simply as the bacterial viruses, even as presaged earlier in experiments with the pox viruses (Beveridge and Burnet, 1946) The second result pointed not only to the possibility of an academic study of changes of mass and substance in infected cell suspensions but also augured the mass production of viral antigens for purposes of production of various viral vaccines The latter possibility has been brought to fruition in the development of various vaccines

However, with these systems it has been found that methodology alone is not sufficient to ensure progress The preparation of animal cells as suitable hosts is far more difficult, expensive and time-consuming than is the preparation of bacterial populations Satisfactory media are not easily definable and are less reproducible Animal viruses are not as readily available nor as easily assayable, they are often more unstable than the phages Infection in vitro is established far less efficiently, and virus yield is proportionately much less. Although great effort is being expended in attempting to overcome these experimental difficulties, progress has been disappointingly slow As a consequence, the biochemistry of animal virus infection is distinguished for the most part by the paucity of its data It will be the task of workers in this decade to bring our knowledge of the animal viruses up to the level of information available concerning bacterial virus multiplication Such an advance requires a great development of our knowledge concerning the nutrition, growth, genetics, biochemistry and physiology of animal cells grown in vitro, i e, tissue cultures In this instance, progress in animal virology will also provide great benefits for the future of cellular physiology and biochemistry

In the past several years much study has been given to the nutritional requirements of isolated mammalian cells (Stewart and Kirk, 1954, Eagle, 1955) and to their biochemical properties (Siminovitch and Graham, 1956; Siminovitch et al, 1957), to the conditions for developing clones from single cells from normal human tissues (Puck et al, 1956, Marcus et al, 1956) and to the cytologic and biochemical stability of such cell lines (Puck and Fisher, 1956) Such studies have been an essential preliminary to the development of optimal experimental systems for the study of viral multiplication For example, the effects of x-irradiation on carefully controlled human tissue cultures have been examined systematically, and it has been reported that cells damaged in this way become particularly susceptible to virus action (Puck and Marcus, 1956)

The requirements for advance in animal virology may call for the development of little-plumbed fields of biologic and chemical study For example, insect virus systems appear to provide the best instances of latency among animal virus systems Recognition of this opportunity has led to renewed effort on the cultivation of insect cells in vitro (Wyatt, 1956) In the systematic analysis of hemolymph as an approach to the development of nutritive media, it was found that, unlike the situation in mammalian sera, which contain free glucose, large amounts of phosphorylated sugars are normal constituents of hemolymph (Wyatt et al, 1956)

Although much is known of the properties of some isolated plant viruses (Chap 2), the analysis of their intracellular multiplication has advanced rather haltingly In large part this has arisen from the difficulties of assay and of establishing infection simultaneously in large numbers of plant cells. These problems of establishing suitable biologic materials have not yet been solved for plant virus systems Until they are, knowledge in this area will be highly unbalanced, and the plethora of information on plant virus structure can lead only to hypotheses whose definitive test will be difficult to achieve

Therefore, we are confronted with 3 levels of knowledge on the biochemistry of virus infection, the levels corresponding to the 3 main groups of viruses: virus-infected bacteria, animals, and plants With each group the state of available data has been determined roughly by the experimental biology developed in each area Although one approach to the presentation of these data could involve a systematic treatment of the known biochemistry of each virus type, we prefer to anticipate the development of a biochemistry of animal virus infection by discussing the kinds of experiments which have already been useful in analyzing infected cells. In so doing, although we shall draw heavily on the most advanced area, that of the bacterial viruses, it will be seen that the fields represented by the animal and plant viruses are not entirely barren.

THE CHEMICAL COMPOSITION OF VIRUSES

A detailed exposition of the chemical and physical properties of viruses is presented in Chapter 2 Several generalizations appear from this data which have been of considerable value in orienting studies on the bio-

tions, e g, the pox viruses, such as vaccinia virus, are larger than pleuropneumonia organisms Most viruses are larger than most proteins, although again it may be noted that a snail hemocyanin is larger than the virus of foot-and-mouth disease. This range of sizes suggests that most viruses possess a structural and chemical complexity which is less than that of cells and greater than that of a protein Until the present, the physical and chemical characterization of isolated virus particles has confirmed this. All viruses contain at least nucleic acid, in addition to protein However, whereas all cells contain two types of nucleic acid, deoxyribose nucleic acid (DNA), which is a characteristic component of chromosomes, and ribose nucleic acid (RNA), which is the only nucleic acid found in the cytoplasm of most cells, all known viruses appear to contain only one or the other type of nucleic acid The few exceptions to this rule appear to occur among the rickettsiae and the psittacosis-lymphogranuloma group of agents, some of which contain both types of nucleic acid and are increasingly being excluded from the "true" viruses for this and other reasons.

If viruses are smaller and chemically less complex than the cells they infect, it may be anticipated that they lack many other components essential to independent growth and multiplication, they probably will lack enzymes and numerous metabolic systems of their own, as indeed they do It can be supposed that these deficiencies define the parasitic dependence of a virus upon their host cells, which thereby are called upon to provide the essential metabolites and perhaps even essential enzymes for the synthesis of viral polymers and particles Therefore, it has been of interest to define in considerable detail the composition of virus particles and more particularly the structural and enzymatic deficiencies of these particles. If the formation of compounds which are present in a virus requires the participation of metabolites and enzymes which are absent from the virus but present in the cell, it is reasonable to believe that those particular aspects of host metabolism have been diverted to virus production and hence are of special interest.

Whether or not such a diversion need be sufficient to affect normal cell function may be approached at least superficially from a knowledge of the metabolic requirements of the normal cell and the extent of synthesis of virus components and virus in the infected cell However, such mass relations need not reflect the true relations of the diverted metabolism, since conceivably a diversion of a small percentage of host energy and product, occurring at a crucial site, may affect a critical portion of the host economy and cellular integrity. In variants of the tobacco mosaic disease, almost 70 per cent of the protein elaborated consists of virus protein, while only

mild stunting of the plant can be seen On the other hand, in tobacco ring spot disease, very small amounts of virus production are accompanied by cell destruction Nevertheless, in the search for key sites of cellular economy, it is important to know the extent of diversion of the infected cell to virus production

It may be noted in brief summary of the chemical data, that all viruses contain protein and one type of nucleic acid All known bacterial viruses contain DNA, and all isolated plant viruses contain RNA (Cohen, 1955). Until recently, all known insect viruses were found to contain DNA, and since some plant viruses are known to multiply in both plants and their insect vectors, the question of the nature of their nucleic acid presented an intriguing problem However, an insect virus has recently been found containing RNA (Zeros, 1956) The animal viruses may contain either RNA or DNA, thus, influenza virus contains RNA, and vaccinia virus and rabbit papilloma virus contain DNA Such studies have suggested that the nucleic acid metabolism of virus-infected cells might be particularly altered to favor the production of the type of nucleic acid characteristic of virus The value of such an educated guess concerning a potentially fruitful area of study is exemplified by studies of bacteria infected by phage in which a tremendous distortion of the pattern of nucleic acid metabolism was revealed, with the shift of synthesis occurring toward the formation of viral DNA (Cohen, 1947)

The analysis of fine structure of virus nucleic acids and proteins has been of considerable value in pointing to interesting metabolic experiments Three examples may be given. The DNA of T-even phages has been found to contain a unique pyrimidine, not known in the host bacterium (Wyatt and Cohen, 1953) As is described below, the problems of the role of 5-hydroxymethylcytosine, the origin of this compound and of the enzyme controlling its synthesis, appear to be central to the parasitism of the T-even viruses.

If the base compositions of the RNA of normal tobacco leaves and of tobacco mosaic virus are compared, it is found that the uracil content of virus RNA is almost twice that of the normal RNA (Reddi, 1956) Metabolic studies have revealed that the availability of uracil is limited during virus multiplication (Basler and Commoner, 1956) and uracil analogues, such as 2-thiouracil, have been most potent in inhibiting the multiplication of tobacco mosaic virus (Jeener, 1957).

Amino acid analyses have been recorded of the virus-producing polyhedral disease of the silkworm, and of the intimate developmental membrane and the capsular proteins of the virus (Bergold and Wellington, 1954) It has been shown that each of these structures produced in virus-infected cells may be distinguished by its content of amino acids From this, it may be inferred that the specific protein metabolism of the infected cell will vary as a function of the particular stage of infection under examination, and of the viral structure being produced at that stage

It has been reported that other structural components, such as lipids and polysaccharides, are contained in some viruses, such as ornithosis and influenza viruses In the first instance, since ornithosis virus is a member of the psittacosis-lymphogranuloma group, it may be asked if the term "virus" is appropriate In the second case, it should be noted that purified preparations of influenza virus contain antigens which cross-react with antisera to normal host components (Cohen, 1944, Knight, 1946) It is not known whether such normal antigens are simply admixed contaminants, adsorbed complexes, or exist as integral portions of the virus Therefore, it is not known if the lipid or polysaccharide of influenza virus are merely components of normal host antigen or are more intimately associated with virus duplication One approach to this problem could ask if the lipid and RNA of influenza virus have comparable origins in time in infected cells, a question which is readily answered with modern technics At the present time, with the exception of some unusual carbohydrate components of T_2 bacteriophage, it is not known that any constituents, other than nucleic acid and protein, reported to exist in viruses, are indeed involved in the duplication of virus substance

The viruses contain proteins are these proteins catalytically active, i e, do they contain enzymes? Parasitic bacteria are usually deficient in only one or a few of the key protein

capable of generating their own high-energy compounds, such as adenosine triphosphate from some energy-yielding process by which respiration or dehydrogenation is coupled to the formation of a high-energy compound In recent years, the rickettsiae have been found capable of oxidizing glutamate and of generating adenosine triphosphate in the process (Bovarnick, 1956; Karp, 1954). This metabolic

Although much is known of the properties of some isolated plant viruses (Chap 2), the analysis of their intracellular multiplication has advanced rather haltingly. In large part this has arisen from the difficulties of assay and of establishing infection simultaneously in large numbers of plant cells These problems of establishing suitable biologic materials have not yet been solved for plant virus systems Until they are, knowledge in this area will be highly unbalanced, and the plethora of information on plant virus structure can lead only to hypotheses whose definitive test will be difficult to achieve

Therefore, we are confronted with 3 levels of knowledge on the biochemistry of virus infection, the levels corresponding to the 3 main groups of viruses - virus-infected bacteria, animals, and plants With each group the state of available data has been determined roughly by the experimental biology developed in each area Although one approach to the presentation of these data could involve a systematic treatment of the known biochemistry of each virus type, we prefer to anticipate the development of a biochemistry of animal virus infection by discussing the kinds of experiments which have already been useful in analyzing infected cells In so doing, although we shall draw heavily on the most advanced area, that of the bacterial viruses, it will be seen that the fields represented by the animal and plant viruses are not entirely barren

THE CHEMICAL COMPOSITION OF VIRUSES

A detailed exposition of the chemical and physical properties of viruses is presented in Chapter 2. Several generalizations appear from this data which have been of considerable value in orienting studies on the biochemistry of infected cells, as well as suggesting an exploration in greater depth of particular aspects of the composition of viruses.

Most viruses are smaller than most microorganisms, although there are a few exceptions, e.g, the pox viruses, such as vaccinia virus, are larger than pleuropneumonia organisms Most viruses are larger than most proteins, although again it may be noted that a snail hemocyanin is larger than the virus of foot-and-mouth disease. This range of sizes suggests that most viruses possess a structural and chemical complexity which is less than that of cells and greater than that of a protein. Until the present, the physical and chemical characterization of isolated virus particles has confirmed this. All viruses contain at least nucleic acid, in addition to protein However, whereas all cells contain two types of nucleic acid, deoxyribose nucleic acid (DNA), which is a characteristic component of chromosomes, and ribose nucleic acid (RNA), which is the only nucleic acid found in the cytoplasm of most cells, all known viruses appear to contain only one or the other type of nucleic acid. The few exceptions to this rule appear to occur among the rickettsiae and the psittacosis-lymphogranuloma group of agents, some of which contain both types of nucleic acid and are increasingly being excluded from the "true" viruses for this and other reasons

If viruses are smaller and chemically less complex than the cells they infect, it may be anticipated that they lack many other components essential to independent growth and multiplication, they probably will lack enzymes and numerous metabolic systems of their own, as indeed they do. It can be supposed that these deficiencies define the parasitic dependence of a virus upon their host cells, which thereby are called upon to provide the essential metabolites and perhaps even essential enzymes for the synthesis of viral polymers and particles. Therefore, it has been of interest to define in considerable detail the composition of virus particles and more particularly the structural and enzymatic deficiencies of these particles. If the formation of compounds which are present in a virus requires the participation of metabolites and enzymes which are absent from the virus but present in the cell, it is reasonable to believe that those particular aspects of host metabolism have been diverted to virus production and hence are of special interest.

Whether or not such a diversion need be sufficient to affect normal cell function may be approached at least superficially from a knowledge of the metabolic requirements of the normal cell and the extent of synthesis of virus components and virus in the infected cell However, such mass relations need not reflect the true relations of the diverted metabolism, since conceivably a diversion of a small percentage of host energy and product, occurring at a crucial site, may affect a critical portion of the host economy and cellular integrity. In variants of the tobacco mosaic disease, almost 70 per cent of the protein elaborated consists of virus protein, while only

mild stunting of the plant can be seen On the other hand, in tobacco ring spot disease, very small amounts of virus [illegible]

[illegible] summary of the chemical data, that all viruses contain protein and one type of nucleic acid All known bacterial viruses contain DNA, and all isolated plant viruses contain RNA (Cohen, 1955). Until recently, all known insect viruses were found to contain DNA, and since some plant viruses are known to multiply in both plants and their insect vectors the question of the nature of their nucleic acid presented an intriguing problem However, an insect virus has recently been found containing RNA (Zeros, 1956) The animal viruses may contain either RNA or DNA, thus, influenza virus contains RNA, and vaccinia virus and rabbit papilloma virus contain DNA Such studies have suggested that the nucleic acid metabolism of virus-infected cells might be particularly altered to favor the production of the type of nucleic acid characteristic of virus The value of such an educated guess concerning a [illegible] is even [illegible] by pha[illegible] of the [illegible] revealed [illegible] toward [illegible] DNA (Cohen, 1947)

The analysis of fine structure of virus nucleic acids and proteins has been of considerable value in pointing to interesting metabolic experiments Three examples may be given. The DNA of T-even phages has been found to contain a unique pyrimidine, not known in the host bacterium (Wyatt and Cohen, 1953) As is described below, the problems of the role of 5-hydroxymethylcytosine, the origin of this compound and of the enzyme controlling its synthesis, appear to be central to the parasitism of the T-even viruses

If the base compositions of the RNA of normal tobacco leaves and of tobacco mosaic virus are compared, it is found that the uracil content of virus RNA is almost twice that of the normal RNA (Reddi, 1956) Metabolic studies have revealed that the availability of uracil is limited during virus multiplication (Basler and Commoner, 1956) and uracil analogues, such as 2-thiouracil, have been most potent in inhibiting the multiplication of tobacco mosaic virus (Jeener, 1957)

Amino acid analyses have been recorded of the virus-producing polyhedral disease of the silkworm, and of the intimate developmental membrane and the capsular proteins of the virus (Bergold and Wellington, 1954). It has been shown that each of these structures produced in virus-infected cells may be distinguished by its content of amino acids From this, it may be inferred that the specific protein metabolism of the infected cell will vary as a function of the particular stage of infection under examination, and of the viral structure being produced at that stage

It has been reported that other structural components, such as lipids and polysaccharides, are contained in some viruses, such as ornithosis and influenza viruses. In the first instance, since ornithosis virus is a member of the psittacosis-lymphogranuloma group, it may be asked if the term "virus" is appropriate In the second case, it should be noted that purified preparations of influenza virus contain antigens which cross-react with antisera to normal host components (Cohen, 1944, Knight, 1946) It is not known whether such normal antigens are simply admixed contaminants, adsorbed complexes, or exist as integral portions of the virus Therefore, it is not known if the lipid or polysaccharide of influenza virus are merely components of normal host antigen or are more intimately associated with virus duplication One [illegible] to this probl[illegible] of inf[illegible] time [illegible] readil[illegible] modern technics At the present time, with the exception of some unusual carbohydrate components of T_2 bacteriophage, it is not known that any constituents, other than nucleic acid and protein, reported to exist in viruses, are indeed involved in the duplication of virus substance

The viruses contain proteins are these proteins catalytically active, i e , do they contain enzymes? Parasitic bacteria are usually deficient in only one or a few of the key protein catalysts, and their parasitic existence appears to depend on their ability to obtain one or another complex intermediary metabolite from their host. However by and large they are capable of generating their own high-energy compounds, such as adenosine triphosphate from some energy-yielding process by which respiration or dehydrogenation is coupled to the formation of a high-energy compound In recent years, the rickettsiae have been found capable of oxidizing glutamate and of generating adenosine triphosphate in the process (Bovarnick, 1956, Karp, 1954). This metabolic

activity, in addition to the presence of both DNA and RNA, a cellular morphology, and a sensitivity to certain antibacterial agents have served to eliminate these parasites from the category of the viruses. Most recently meningopneumonitis "virus" has been found to contain a DPNH-cytochrome C reductase (Allen and Bovarnick, 1957), an activity, which in conjunction with the large size of the agents of the psittacosis-lymphogranuloma group, their inhibition by antibiotics, and their complex growth cycle, has suggested their closer relation to the parasitic cells.

On turning to the true viruses, it should be noted that most assays for their possible enzymes were performed at a time (over 15 years ago) when only a limited number of systems, active in respiration, hydrolytic cleavages of various types, and some limited areas of carbohydrate metabolism could be determined In summary of this data, it may be said that no enzymatic component of an electron transport system has yet been observed in any plant, animal or bacterial virus, nor have any changes in the respiration of infected cells been noted to suggest the presence of a respiratory system in newly multiplied virus particles (Cohen, 1957; Gottschalk, 1957) However, vaccinia virus, although lacking the cytochromes and a variety of dehydrogenases, has been found to contain a coenzyme, flavin adenine dinucleotide, important in electron transport It must be asked, therefore, if in this virus a flavoprotein enzyme does not exist capable of carrying out some as yet undetermined reaction The added presence of copper and biotin in this virus poses the same question (Smadel and Hoagland, 1942)

Despite the apparent presence of these substances in vaccinia elementary bodies, tobacco mosaic virus and T_6 bacteriophage are not considered to contain significant amounts of the various coenzymes which embody biotin, pantothenic acid, riboflavin, folic acid, nicotinic acid and vitamin B_{12} (Sprince and Schoenbach, 1942; Kleinschmidt et al, 1956). The amount of acid-soluble phosphorus in these viruses is so low (1% or less of the total P) as to raise doubts concerning its reality as non-nucleic acid phosphorus In the absence of significant amounts of internal intermediary metabolites in the viruses, it has been suggested that the cell supplies the metabolites essential for viral polymer synthesis, since the viruses neither contain these substances nor have been found to be capable of any reaction which will provide essential metabolites or energy-rich compounds important in the fabrication of essential metabolites.

On the other hand, since the mechanisms of synthesis of polymeric nucleic acids and proteins are barely beginning to be clarified, it cannot be said with certainty that, given the essential metabolites, the viral polymers are incapable of catalyzing their own duplication. At the present time, the test of such a hypothesis cannot be designed nor can the appropriate metabolites be afforded.

As described in Chapter 2, the infectivity of various virus particles appears to reside in their nucleic acid components. To the extent that infection of host cells may be initiated by the nucleic acids alone, the problem of the synthesis of virus polymers must be posed in terms of (A) the polymer synthesizing enzymes of the host cells or (B) the possible activities of viral nucleic acids rather than viral proteins, or (C) the host enzymes and nucleic acid templates acting in unison to produce viral polymers or alternatively to produce new enzymes which are then capable of synthesizing the viral polymers. The problem of who does what in the fabrication of viral substance must be raised at 3 structural levels at least, that of (1) the small building blocks of the amino acids and nucleotides, (2) the polymeric viral proteins and nucleic acids and (3) the organization of the latter components to form the familiar isolated virus particles Although at the lowest structural level the responsibility of supply appears to rest with enzymes of the normal cell, we shall see certain instances in which key small building blocks are provided by enzymes of neither cell nor virus alone but rather by enzymes generated in the infected cells It is not certain that the intermediate levels of synthesis require enzymes in the sense in which they are commonly defined as catalytic proteins, and for tobacco mosaic virus at least the final assembly of nucleic acid and protein can occur as a nonenzymatic reaction (Chap 2)

Many hydrolytic systems are absent from the viruses Occasional reports of phosphatase activity, etc, have been attributed to contamination of the virus preparation under investigation However, an adenosine triphosphatase has been found to be intimately associated with the virus of avian myeloblastic leukosis (Mommaerts et al., 1954). Nevertheless, the significance of this association is obscured by the fact that the isolated virus particles contain normal chick antigens (Eckert et al, 1955a) Furthermore, the rates of thermal inactivations of enzyme and infectivity were significantly different, indicat-

ing at least the lack of identity of the centers for infectivity and enzyme activity (Eckert et al., 1955b). The role of the ATPase in the development of this virus infection is most obscure at present.

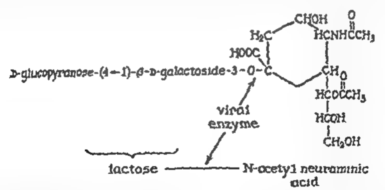
In two instances hydrolases, having important roles in the life cycles of the viruses, have been detected in virus particles (Gottschalk, 1957). As is described in Chapter 7, it has been shown that the tail of T-even bacteriophages contains an enzyme which helps to puncture the cell wall of *Escherichia coli*. Attachment of the virus to the bacterium exposes the viral enzyme which releases nitrogenous material from the cell wall (Barrington and Kozloff, 1956, Koch and Weidel 1956). Although it is suspected that the viral enzyme is a proteinase which cleaves peptide bonds, this has not yet been proved rigorously, since a well-defined substrate for the viral enzyme is not yet available.

Influenza virus also contains an enzyme which releases virus from its combination to erythrocyte surfaces after adsorption. The receptor at the red cell and other cell surfaces is thus considered to be the substrate for the viral enzyme. Better-defined substrates for this enzyme have been obtained, and these contain in each case a derivative of neuraminic acid, a compound which appears to be a basic unit contained in animal cell membranes. One such defined substrate is neuramin-lactose, possessing the following structure

In this interesting case, the study of the enzymatic activity of influenza virus has made important contributions to the analysis of the structure of animal cell surfaces and has created a bridge between the problem of virus growth and a host of other problems involving the structure and the function of cell surfaces.

COMPARATIVE ASPECTS OF VIRAL MULTIPLICATION

As the chemical and morphologic data indicate, the viruses are not a homogeneous group. It has been seen that many pl[illegible] [illegible] stru[illegible] chemical machinery to assist in the penetration of the well-protected plant cell. The penetration of new plants by virus may occur as a result of the infection by insects or after other abration of plant surfaces. On the other hand, the bacterial viruses have at their tail tip a single point of attachment to the bacterial receptors of the rigid cell wall. The interaction of cell wall and the viral tail tip in at least the T-even systems leads in sequence to the uncovering of a viral enzyme which opens a hole in the cell wall, extrusion of the viral tail spike, and injection of viral DNA into the bacterium. Unlike plant viruses



By cleaving the glucosyl linkage indicated above, the viral enzyme releases N-acetyl neuraminic acid or sialic acid from this and more complex substrates; therefore, it is termed a neuraminidase (Gottschalk, 1957). It has been suggested that the viral enzyme is not important in the penetration of the virus into the cell but rather is active in the escape of the virus through the cell surface

without any points of attachment or bacterial viruses with a single point of attachment, many animal viruses possess multiple points of attachment to cell receptors. This is revealed by the phenomenon of hemagglutination in which a virus particle may serve as a bridge connecting erythrocytes or in some instances separated host cells in tissue cultures

(Scherer, 1952) Thus, although a single antibody molecule is sufficient for the inactivation of Newcastle disease virus, such inactivated virus particles can adsorb to host cells. Several such molecules are required to prevent adsorption of the virus to the host (Rubin and Franklin, 1957). After attachment of the virus particle the surface membrane of the animal cells is considered to be capable of enveloping the virus particle and fulfills an active role quite unlike that of the corsetlike plant or bacterial cell wall.

The liberation of various viruses from infected cells also appears to vary as a function of the surface structure of the various types of host cells involved. Thus, the removal of a plant virus from a plant requires the rupture of the tough plant cell walls by the penetration of insect mouth parts or of a parasitic plant such as dodder. Spread of virus within the plant may be effected by intracellular plasmodesmata, thereby obviating the need of an additional rupture of the cell wall in passing from one cell to another. However, in bacterial virus systems, virus liberation always involves lysis of the cell wall and cell destruction. Very little is known about the mechanisms of this phenomenon. In animal virus systems, several mechanisms appear to be operative. Some workers have postulated the spread of virus from one cell to another by intracytoplasmic threads. In other cases, notably influenza virus systems, virus extrusion is clearly associated with the development of long virus-containing filaments on the surface membrane and their liberation without cell rupture. Unlike the bacterial viruses in which the liberation of all phages from a single cell occurs simultaneously with cell lysis, the liberation of various animal viruses from a given cell may be a slow process taking many hours (Henle, 1953, Dulbecco and Vogt, 1954; Rubin et al., 1955). In other cases, the development of plaques in tissue cultures infected by poliomyelitis virus, vaccinia virus, herpes virus, etc., indicates the spread of infection at least in part by a lytic mechanism of release as in the bacterial virus systems. However, it is by no means evident that the intracellular spread of any of these animal viruses occurs in vivo predominantly as a result of a lytic release.

The heterogeneity of the viruses is also clearly revealed in the analysis of the patterns of viral parasitism, which extend from systems in which infection leads almost exclusively to the synthesis of virus to those in which infection permits both virus and host cell to multiply together. In the former pattern, best exemplified by the effect of the T-even phages on the host *E. coli*, strain B, the nuclear apparatus is destroyed, and the metabolism of the host is diverted to the synthesis of large amounts of specific virus substance. Virus particles accumulate within the cell and are liberated by lysis. In the latter pattern, exemplified by the effect of phage lambda which infects *E. coli*, strain K_{12}, the virus may, depending upon environmental conditions, take a virulent path like that of the T-even phages, or alternatively, in a temperate cycle associate its genetic apparatus with that of the host cell and multiply in unison with it. In certain instances this symbiotic or lysogenic relationship may be disrupted by external stimuli, such as treatment by ultraviolet radiation or carcinogens. The phage then begins a maturation and uncontrolled multiplication leading to the accumulation of virus particles and cell lysis.

In these systems virulence leading to cell lysis produces an extracellular phase of virus existence in which the hereditary determinants of the phages are protected by a tough protein coat resistant to the enzymes, the proteases and the nucleases, which are liberated by lysing bacteria. In addition, as noted above, this coat is also highly differentiated for purposes of transferring the nucleic acid charge of the virus through the tough bacterial cell wall and is shed from the genetic material prior to its intracellular multiplication. Similarly, the protein coat of a lysogenic phage is not found during its reproduction as a prophage on the bacterial chromosome, or as vegetative phage after induction. Thus, these differences in the patterns of virulent and temperate infection greatly influence phenomena of protein synthesis.

In the bacterial viral systems the hereditary determinants of the virus are DNA and therefore are similar to nuclear determinants. This identity may be taken to suggest that in these systems we are dealing with aberrant nuclei or chromosomes. Certainly virulent phage multiplication results in the degradation of

the bacterial nucleus and DNA (Luria and Human, 1950). In plant virus systems, it appears that the RNA of the virus is the genetic material which is also shed from its protein coat Indeed, it is possible that, in the transmission of infection within a plant by intracytoplasmic bridges, the free RNA of tobacco mosaic virus may be the predominant unit of infectivity Since the plant viruses are found mainly in the cytoplasm and in containing RNA exclusively, more nearly resemble cytoplasmic units, it has been suggested that these viruses perhaps arise as aberrant cytoplasmic units, as in the variegation of plastids In the plant virus systems then, the metabolic alterations which might be explored initially and most fruitfully might be those expected in a cytoplasmic disease Thus, if electron microscopy suggests that beet yellows virus may originate in a diseased chloroplast (Leyon, 1953), one might explore the photosynthesis of normal and diseased cells and chloroplasts, as well as their synthetic capabilities toward RNA and protein

How shall we look at the animal viruses? Most of the known insect viruses produce nuclear inclusions and contain DNA It can be anticipated that the effects of infection in these systems will be quite different from those of the RNA-containing insect virus which produces cytoplasmic polyhedrosis

The study of infectious viral papilloma of human skin has also led to the observation of intranuclear DNA-containing inclusion bodies This in turn pointed to the desirability of a cytochemical study of DNA and histone production in infected cells at different developmental stages (Bloch and Godman, 1957) Many of the adenoviruses produce intranuclear inclusions which contain crystalline arrays of DNA-containing particles (Morgan et al, 1956, Bloch et al, 1957, Boyer et al, 1957) The existence of such particles points to DNA metabolism as a critical area of study in infection by these viruses

Briefly then, determination of the sites of virus synthesis and multiplication should be quite useful in orienting biochemical work In some instances, localization of these viruses within the cells can pose certain problems quite sharply For example, vaccinia virus which contains DNA appears to reproduce in the cytoplasm. Then it may be asked if this virus contains a system capable of synthesizing deoxyribose polynucleotides or are polynucleotide fragments of this nucleic acid preformed in the cell nucleus and then transferred to the cytoplasm where the virus organizes these pieces into virus DNA (Gaylord and Melnick, 1953, Morgan et al, 1954)

However, it cannot be supposed that existing data are sufficient in all virus diseases to orient the biochemical approaches to the infected cell For example, viruses of the influenza group are now known to contain RNA, antigens related to cytoplasmic constituents, and are often liberated in surface filaments It might be supposed that these viruses are entirely cytoplasmic in origin However, striking studies by means of fluorescent antibodies on production of viral antigen have revealed extensive nuclear involvement in the production of the nucleoprotein antigen of influenza and fowl plague viruses (Watson and Coons, 1954, Breitenfeld and Schafer, 1957). DNA changes in the nuclei of influenza virus-infected cells have also been reported, thereby implicating this substance as well in the multiplication of an RNA virus (Wolff, 1957) Nuclear and DNA changes have been observed recently in poliomyelitis-infected cells as well (Tenenbaum, 1957) It is clear then that the elucidation of the cellular site of virus multiplication is often a problem in its own right whose solution is useful in the evolution of a suitable cellular orientation to the biochemistry of a specific virus infection

METHODOLOGY IN THE STUDY OF INFECTION

Obviously, the elucidation of biochemical events in the course of infection may be accomplished by the chemical analysis of the changes in the components in infected cells Until the present, such an approach has improved only slowly in the chemical finesse and delicacy of its dissection, since this type of problem has not yet attracted many skilled biologically oriented chemists In lieu of this type of direct approach, biochemical information may be obtained less directly by studying the effects of environmental change on the biology of virus production When, in addition, either of these approaches is combined with morphologic analysis, as performed by skillful electron microscopists, the derivable

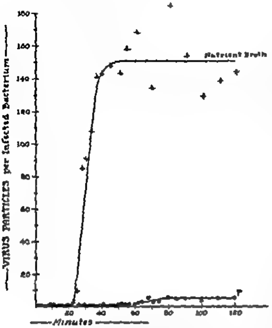


FIG 19 One-step growth curves for T2+ bacteriophage in broth-grown bacteria in broth and synthetic media (F) (Fowler, C B, and Cohen, S S, 1948, Chemical studies in host-virus interactions IV A method of determining nutritional requirements for bacterial virus multiplication, J Exper Med 87, 259-274)

biochemical information is accorded an additional dimension. It is precisely in the field of virology, which is concerned with genetic duplication at molecular and intermolecular levels, that chemical dimension meets biologic dimension most clearly, in this field, electron microscopy, even in its current development, becomes a tool for the analysis of both chemical and biologic structure

It is immediately evident that a study in which detectable chemical changes are correlated with both biologic and morphologic data will provide the best information on the course of virus multiplication Such a study depends on the development of methods for opening cells to liberate biologically significant units. In the field of the bacterial viruses, a number of technics have been devised to break open infected cells. One of the earliest of these used cyanide to provoke autolysis and liberation of virus and revealed that intact virus particles could not be observed in infected cells until about the second half of the latent period of multiplication (Doermann, 1948; 1952). A joint examination of DNA synthesis and the appearance of intact virus in infected bacteria demonstrated that several minutes intervened between the two functions, i e, that the formation of DNA did not complete virus formation (Cohen, 1949). Subsequent analyses of the kinetic relations of the newly synthesized DNA and the intact virus particles have been performed by Hershey (1953) and are discussed in some detail in Chapter 7.

In the field of animal viruses, a number of workers have studied the relationship of the

particles The appearance of these newly formed biologically active units poses the problem of their definition to the chemists. *Examples of these kinetic studies are presented in later chapters*

From these types of analysis, which are in their infancy, a general pattern of virus multiplication has emerged which is typified by that observed in bacterial virus systems Biologically unique components of virus are found before intact virus particles and indicate the existence of terminal steps of assembly after a long series of synthetic reactions Unlike the multiplication of cells in which the cell maintains its integrity and capacity for multiplication throughout its life cycle, the viruses

acteristics only at the end of a large number of intermediate steps

CHEMICAL EFFECTS ON VIRUS MULTIPLICATION AND YIELD

In the approaches to the biochemistry of viral-infection to be considered immediately below, the number of infectious virus particles and the rate at which they are produced are used as a biologic measure of biochemical processes. In a few studies, it will be seen that changes in the quality of the particles produced are also sought and detected, as in an increased production of mutations or otherwise modified or deficient particles

NUTRITIONAL REQUIREMENTS

The environment essential for the multiplication of any virus consists of the interior of a cell, which in turn will tend to be modified by variations in the external environment of

the cell Only the external environment can be varied controllably and directly, and this can be done to affect not only the environment in which the virus is produced but the uninfected host cell as well. Under certain conditions it is possible to alter the enzymatic complement [redacted]f the uninfected host cell, creating deficiencies which may be used to explore requirements for virus multiplication A more common alternative approach is to vary the environment surrounding the infected cells. Examples of results obtained by both technics will be given

Two basic experiments with bacterial virus systems exemplify the types of results to be obtained Bacteria, e.g , *E. coli*, may be grown in broth, which contains a wide variety of metabolites, and minimizes the necessity of the cell to develop enzymes for the production of many of these compounds When such enzymatically deficient bacteria are resuspended in media containing broth, or mineral salts and a simple compound such as lactate or glucose as sole carbon source, it [redacted] found that on infection in these media, broth supports a far greater production of virus in a shorter time than does the simple medium (Cohen, 1949) As shown in Figure 19, cells grown in broth are poorly equipped to produce virus in a medium containing lactate as sole carbon source It may be inferred that in this system the cell uses many exogenous metabolites in the synthesis of virus components Supplementation of the lactate medium with an amino acid hydrolysate plus nucleic acid derivatives permits virus multiplication to about the level supported by nutrient broth (Fowler and Cohen, 1948)

Given a completely defined medium which can support a high level of virus multiplication in broth-grown bacteria, it [redacted] now possible to determine the effect of omitting single constituents, as in Figure 20 It can be seen from this experiment that exogenous tryptophan and leucine are important for T_2r^+ virus multiplication in this system. Further-

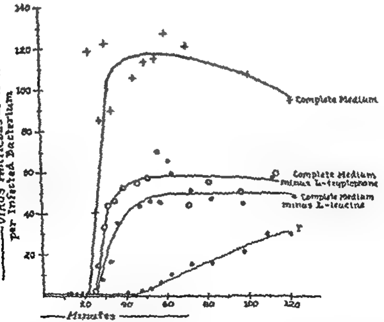

FIG 20 One-step growth curves for T2r+ in broth-grown bacteria in media of different compositions (Cohen, S S , and Fowler, C [redacted], 1948, Chemical studies in host-virus interactions V. Some additional methods of determining nutritional requirements for virus multiplication, J Exper Med *87*, 275-282)

more, it can be shown by chemical estimation that the synthesis of virus nucleic acid is inhibited under conditions of such restriction of single amino acids (Cohen and Fowler, 1948)

In extending this approach to animal virus systems, it has been found that tissue cultures of minced chicken embryos maintained in inorganic salts and glucose for up to 15 days can then be infected with psittacosis virus without virus production Supplementation of these cultures by a mixture of amino acids, nucleic acid derivatives and other compounds permits the elaboration of virus As seen in Figure 21, if selected single components, such as phenylalanine or tryptophan, were omitted from the complex mixture, virus multiplication did not occur (Heggie and Morgan, 1956). The development of synthetic media for the growth of animal cells and the production of virus in such cells have already permitted the demonstration of the requirements for exogenous glucose and glutamine in the optimal production of poliomyelitis virus in human cells, such as the HeLa cell (Eagle and Habel, 1956)

Effects of Inhibitors

Various inhibitors and antimetabolites have been found to be useful, not only in imposing deficiencies on infected cells, but they furnish greater potentialities for the dissection of the multiplication cycle than do the simple nutritional technics. Thus, it is possible to infect in the presence of an inhibitor whose action can be reversed at some later interval by the addition of an appropriate metabolite. Alternatively, the inhibitor itself may be used to interrupt later stages of multiplication which can then be restarted with metabolites In such experiments, a careful study of virus production and liberation will reveal whether the inhibitor does indeed affect a process essential to virus multiplication during the period in which the infected cell was exposed to its action. Such studies with inhibitors relate not only to the apparently academic problem of understanding details of the infectious cycle of a virus but are evidently of considerable interest in developing a chemotherapy of viral infection.

The use of citrate to bind calcium ions has

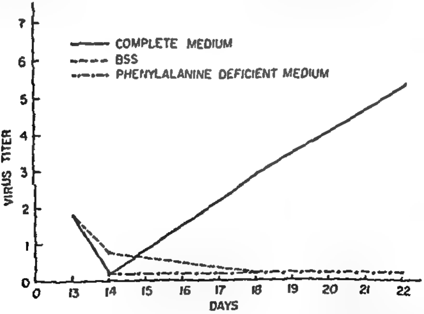

Fig. 21 The effect of phenylalanine deficiency on the stimulation of growth of psittacosis virus in chick embryo tissue culture cultivated in [illegible]

been used to reveal a role for these ions in the adsorption of some bacterial viruses in bacteria. Calcium is also found to be important in early stages of phage multiplication, as summarized by Adams (1954) Similarly, potassium has been found to be important in several stages of multiplication of influenza virus (Levine et al, 1956) Earlier it had been shown that the inhibitor, α-amino-α (p-methoxyphenyl) methane sulfonic acid, affected a very early stage of viral multiplication, as shown in Figure 22 (Ackermann and Maassab, 1954) It was then shown that such an inhibition may be reversed by potassium ions (Levine et al., 1956)

The effects of specific amino acid analogues were first clearly demonstrated in bacterial virus systems It had been shown that 5-methyl tryptophan does not inhibit T-even phage adsorption but does block virus multiplication (Cohen and Anderson, 1946, Fowler and Cohen, 1947) As shown in Figure 23A addition of the analogue in the first half of the latent period completely prevents virus liberation Indeed, when infected cells are held in the presence of the agent they slowly and irreversibly lose the ability to produce virus, a point potentially of interest in the chemotherapy of infection On the other hand, if the agent is added in the second half, multiplication is inhibited, but virus already produced intracellularly is liberated. In Figure 23B it can be seen that the subsequent addition of tryptophan to the cells inhibited at the inception of infection permits the development of a normal period of virus multiplication. Such an experiment shows that the analogue prevents processes requiring tryptophan, presumably protein synthesis, at the very beginning of multiplication It has been shown with this agent and other inhibitors, such as chloramphenicol, as well as in experiments with deficient mutants, that such early protein synthesis is essential to the later synthesis of viral DNA (Cohen, 1947, Burton, 1955, Tomizawa and Sunakawa, 1956, Hershey and Melechen, 1957) Furthermore, as can be seen in Figure 23C, if multiplication is interrupted by 5-methyl tryptophan and restarted by the addition of tryptophan, the processes take up exactly where they left off In this way requirements for an amino acid can be demonstrated throughout various periods of virus multiplication

In a similar way, the effects of compounds such as p-fluorophenylalanine and methoxinine

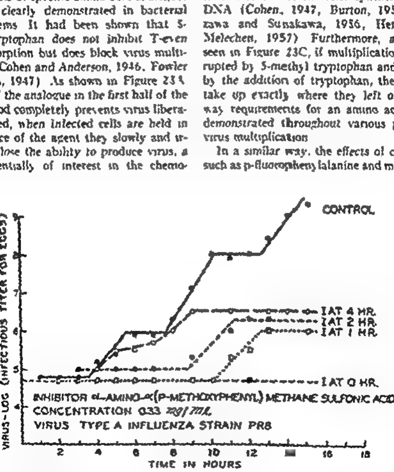

FIG 22 Effect of an inhibitor on the latent period of influenza virus multiplication. (Ackermann, W W, and Maassab, H. F., 1954, Growth characteristics of influenza viruses the influence of sulfonic acid, J Exper Med *99*, 105-117)

more, it can be shown by chemical estimation that the synthesis of virus nucleic acid is inhibited under conditions of such restriction of single amino acids (Cohen and Fowler, 1948)

In extending this approach to animal virus systems, it has been found that tissue cultures of minced chicken embryos maintained in inorganic salts and glucose for up to 15 days can then be infected with psittacosis virus without virus production Supplementation of these cultures by a mixture of amino acids, nucleic acid derivatives and other compounds permits the elaboration of virus As seen in Figure 21, if selected single components, such as phenylalanine or tryptophan, were omitted from the complex mixture, virus multiplication did not occur (Heggie and Morgan, 1956) The development of synthetic media for the growth of animal cells and the production of virus in such cells have already permitted the demonstration of the requirements for [illegible]

D, and Morgan, H. R., 1956, Latent viral infection of cells in tissue culture. III. Role of certain amino acids, Proc. Soc. Exper. Biol & Med., 92, 506-509)

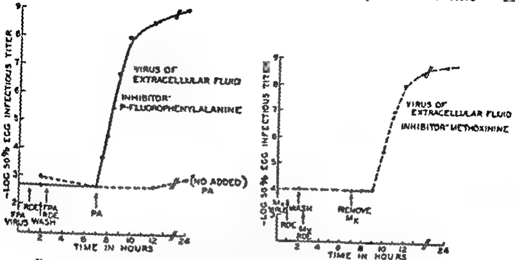

FIG 24 (A, *Left*) The production of the PR8 strain of Type A influenza virus in chorio-allantoic membrane after release of inhibition of p-fluorophenylalanine (FPA) by addition of phenylalanine (PA) The infected tissue was washed with receptor-destroying enzyme (RDE) to prevent readsorption of released virus (B, *Right*) The production of influenza virus after removal of inhibitory methoxinine (Mx) by washing the infected tissue (Ackermann, W W, and Maassab, H F., 1955, Growth characteristics of influenza virus II Biochemical differentiation on stages of development J Exper Med *102*, 393-402)

have been studied on influenza virus multiplication in isolated pieces of chick chorio-allantoic membrane (Ackermann and Maassab, 1955) As shown in Figure 24A, addition of phenylalanine to release the inhibition produced by fluorophenylalanine permits an immediate rapid release of virus, indicating that the inhibitor permits certain essential reactions to continue On the other hand, as shown in Figure 24B, the release of the inhibition produced by methoxinine requires a lag of at least 2 hours before virus release It is evident that this compound is acting more like 5-methyl tryptophan and affects virus multiplication at a point different from that affected by fluorophenylalanine

In studying the inhibition of influenza virus and vaccinia virus by benzimidazole derivatives, it was shown that for the former virus, the most potent inhibitor was a N_1-β-D-ribofuranosyl benzimidazole (Tamm et al , 1956) Such a nucleoside is most likely to affect the production of RNA, the kind of nucleic acid found in the virus On the other hand, in inhibiting the multiplication of vaccinia virus, a DNA virus, the benzimidazole ribosides were only as active as the free benzimidazoles, implying that important aspects of nucleic acid metabolism involved in the synthesis of this virus are different from those observed in the multiplication of influenza virus

Many compounds are now available for the study of the inhibition of virus multiplication Their structures and modes of action have been discussed extensively by Matthews and Smith (1955).

INHERITANCE AND MUTAGENESIS

As discussed in Chapter 2, it is now believed that the information essential to the duplication of viral structure is mainly, if not entirely, coded within the structure of the nucleic acids of the viruses Such a relation of nucleic acid to inheritance was first demonstrated in the transformation of inherited characteristics of pneumococci by means of isolated bacterial DNA, a similar relation of DNA to inheritance has since been extended to many micro-organisms Since the nucleic acids of the T-even bacterial viruses and of tobacco mosaic virus and its strains are infectious and can transmit specific genetic characters of the respective viruses, these substances appear also to embody the viral genetic determinants The isolation of in-

bacteriophage system, J. Exper Med 85, 771-784)

the liberation of T_2 particles. This is interpreted to signify that in mixed infection DNA *characteristic of T_2 may add an adsorptive* tail possessing T_4 proteins. After such phenotypic mixing (Novick and Szilard, 1951), the next generation obtains proteins determined by the T_2 nucleic acid. Thus, the assembly *process is in part conditioned by the environment* of proteins provided within the host cell. This and other host-induced modifications of the viruses have been discussed by Luria (1953).

Hereditary modifications of viruses have not been effected by various treatments of the isolated particles alone. However, such mutations may be made to occur in relatively high frequency by ultraviolet radiation of both virus and host bacteria (Weigle, 1953, Dulbecco, 1953). Jacob (1954) has observed the *increase of mutants by preirradiation of the* host bacterium prior to infection by normal virus. It is evident that derangements of host metabolism can markedly affect the quality of the virus nucleic acid produced.

Treatments of phage-infected bacteria with proflavine (DeMars, 1953) or streptomycin (Fernandez et al., 1953) also increased the percentage of mutations in the emergent progeny. *These agents did not appear to select* the mutants but did induce their formation. The mechanisms of these mutagenic actions are not known, nor have the mutagenic effects themselves been extended to plant or animal virus systems.

In recent years it has been demonstrated that unnatural synthetic purine and pyrimidine bases can be used for the synthesis of viral nucleic acids. Thus, 5-bromouracil will replace thymine in the synthesis of bacteriophage DNA. A number of compounds, including 2-thiouracil in place of uracil, 8-azaguanine in place of guanine, etc., can be inserted into the ribose nucleic acid of tobacco mosaic virus particles.

In the former case, thymine-deficient bacteria may be grown in thymine and infected *with T_2 bacteriophage in the presence of* bromouracil. The emergent progeny contain a very high percentage of inactive particles (about 80%). However, within the population of active particles is found DNA in which *all of the thymine is replaced by bromouracil,* and among such active particles may be found a high percentage of mutants (Litman and Pardee, 1956). Their changed genetic constitution is maintained in subsequent generations, although the unnatural bromouracil is replaced in turn by thymine.

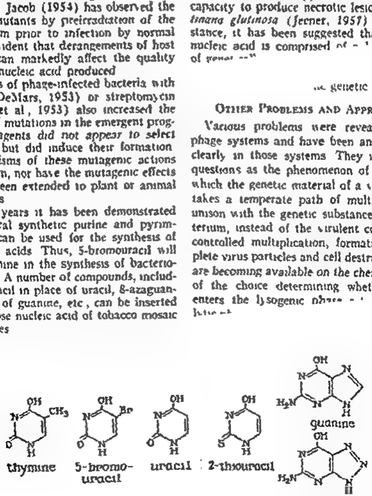
Thiouracil represses the production of tobacco mosaic virus. However, whatever virus is produced contains some of the unnatural base but does not appear to have a lowered capacity to produce necrotic lesions on *Nicotiana glutinosa (Jeener, 1957). In this in*stance, it has been suggested that the virus nucleic acid is comprised of ... of ...

... genetic units.

OTHER PROBLEMS AND APPROACHES

Various problems were revealed first in phage systems and have been analyzed most clearly in those systems. They include such questions as the phenomenon of lysogeny in which the genetic material of a virus particle takes a temperate path of multiplication in unison with the genetic substance of the bacterium, instead of the virulent course of uncontrolled multiplication, formation of complete virus particles and cell destruction. Data are becoming available on the chemical nature of the choice determining whether a virus enters the lysogenic phase ...

... latency



thymine 5-bromouracil uracil 2-thiouracil guanine 8-azaguanine

fectious nucleic acids from virus-infected animal cells has also been reported Indeed, from the point of view of the analysis of the chemical nature of the transmission of the genetic information by isolated nucleic acids, the viral systems may be more suitable than bacterial systems, since the isolated viral nucleic acids are biologically, and presumably chemically, more homogeneous than are the bacterial nucleic acids, i e, they contain many fewer genetic determinants

In all of these studies, the demonstration that a portion of a virus contains such genetic properties is biologic. Cells capable of virus production are exposed to the action of the nucleic acid, and the liberation of virus is detected by indicator host cells In this way when the RNA of one strain of tobacco mosaic virus is combined with the protein of another strain and such reconstituted particles are used to infect a cell, it can be detected that the viral progeny possess the biologic characteristics of the strain that provided the nucleic acid

Until recently, the evidence that the DNA

phage DNA from phage into the cell was demonstrated This is considered in greater detail below However, it proved to be very difficult to show that significant amounts of protein were not also injected into the cell The polymeric DNA of the T-even phages will not penetrate into intact *E. coli* (Cohen, 1947) However, penetration appears to be considerably facilitated by the use of bacterial protoplasts, i.e , bacteria denuded of their cell wall by enzymes and preserved within a naked membrane by hypertonic media Phage particles, disrupted to release their DNA, at least partially, which are inactive in infecting intact bacteria, are reported to be capable of establishing infection in protoplasts (Spizizen, 1957; Fraser et al., 1957) Such capabilities of disrupted particles are destroyed by deoxyribonuclease (DNAase), although this enzyme does not affect intact virus Surprisingly, the infectivity is also destroyed by trypsin, implicating peptide bonds in the infectious principle.

The appearance from infected cells of viruses differing in some inheritable characteristic from the infecting parent may be taken as evidence of some alteration in the composition and the structure of the nucleic acid of the progeny Thus, experiments on mixed infection of one cell with several viruses have revealed the development of individual progeny containing characteristics of the several viruses Several such types of exchange are known and reflect the several ways in which the information derived from the nucleic acid of the several viruses can be used to make a single particle. In experiments in T-even phage systems, it has been observed that from 15 to 25 essential exchangeable genetic units exist within these viruses (Luria, 1947, Delbruck and Bailey, 1946; Doermann et al, 1955) It may then be inferred that various parts of the DNA charge of the virus are biologically and therefore chemically distinct, although conceivably bound in a single chemical unit. The physical bases of such exchange are obscure at present; it is not known whether the exchange involves the exchange of bits of infecting DNA prior to or during multiplication or if the exchange occurs during assembly of the different kinds of units of DNA elaborated in the infected cell.

An in vitro reshuffling of the parts of a viral nucleic acid has been claimed for the nucleic acid of tobacco mosaic virus. Commoner et al (1956) have isolated the nucleic acid of this virus and have combined it with virus protein to give infectious nucleoprotein Such reconstituted particles were then found to give rise to an unusual number of mutant strains. In addition, fractionation of the reconstituted nucleoprotein and comparison with the fractionation of the original nucleoprotein have revealed marked differences in the two populations of particles

Genetic recombination technics in phage-infected bacteria have been used to calculate the linear order of determinants within the linear phage DNA One such study has given rise to the estimate that the chemical unit

controlled by separate genetic determinants which are many recombination units apart, suggesting that these structural features of the tail arise from differences in protein structure controlled by different genetic units (Brenner, 1957)

In experiments in which *E coli* is infected with a mixture of T_2 and T_4 viruses, progeny possessing characteristics of T_4 have been obtained, i.e., they infect cells resistant to T_2 However, occasionally infection with such T_4-like progeny leads in the next generation to

cation have now been fulfilled, no experiments of this character have yet been reported

EFFECTS REVEALED BY CHEMICAL ANALYSIS

Changes of Mass. Given virus-infected cells, the chemical methods which must be employed to detect changes of substances will depend on the quantities involved as well as on the kinds of substance to be examined Under favorable conditions virus-infected bacteria may liberate as many as several hundred virus particles, the dry weight of each of which is of the order of 0 1 per cent of the host cell It is evident then that an infected bacterium (*E coli*-T_2) may synthesize as much as 25 per cent of its mass in virus-specific products However, the changes in constitution of the main classes of intracellular substance will reflect the formation of viral components only if such synthesis is net synthesis, i e, if host substance is degraded and resynthesized to viral material of the same general class, it may not be possible to observe gross changes in the chemical composition of infected cells In the *E coli*-T_2 system, changes are readily detectable by gross analyses T_2-infected cells cease multiplying but continue to synthesize protein at a constant rate The synthesis of DNA stops briefly and then resumes at a rate of several fold (4 and more) that observed in uninfected cells. The RNA content of infected cells remains essentially constant (Cohen, 1947) This point will be considered in greater detail below where it will be shown that the apparent constancy of quantity masks considerable metabolic activity These phenomena are represented in Figure 26A

The changes in components of infected cells can be studied under conditions of abortive infection with damaged virus particles or under the influence of inhibitors, such as proflavin or 5-methyl tryptophan As noted earlier, inhibition of protein synthesis with

Circles with crosses are counts after decompression breakage (B, *Right*) Growth curve of doughnuts (dotted line) and phage (solid line) P-1 means 15 particles per bacterium. (Levinthal, C, and Fisher, H, 1952, The structure development of a bacterial virus, Biochim et biophys. acta 9, 419-429)

in animal viruses are treated in other chapters

Ionizing and ultraviolet radiation have provided important tools in the analysis of virus multiplication Chemical inferences may be drawn from results obtained in this way as discussed in part in later portions of this chapter; however, such data and conclusions are discussed particularly in Chapter 7

COMBINED BIOLOGIC AND MORPHOLOGIC DATA

The advantages of combining the attacks of several disciplines in analyzing virus-infected cells may be recorded in the following examples: Phage-infected bacteria were disrupted by decompression shock, and the exposed internal macromolecular structures of the cell were examined in the electron microscope (Levinthal and Fisher, 1952). As can be seen in Figure 25A, intact virus particles do not begin to appear within the cell until the second half of the latent period The first sign of the formation of new virus is the appearance of the hollow shells of the heads of virus particles These structures have been called "doughnuts" The doughnuts have been shown to contain phage antigens unlike those involved as adsorption sites (Lanni and Lanni, 1953) The relation of the formation of doughnuts to intact phage is given in Figure 25B

In an extension of this study, the contents of infected cells inhibited by proflavin were studied (DeMars et al, 1953) This compound allows lysis of infected bacteria to occur without liberation of infectious phage (Foster, 1948). When such inhibited cells are disrupted at various times after infection, it is found that the doughnuts appear in the bacteria at the usual time but are not replaced by mature virus It was concluded that proflavin affects terminal organizing steps in the completion of phage particles

Although the conditions for such an integrated kinetic study of animal virus multipli-

disappears as virus appears, suggesting that later the new RNA may be incorporated into virus. As pointed out earlier, uracil, unlike the other bases, is limiting in determining the amount of virus synthesized in this system

Very little has been done on the course of virus multiplication in other plant systems. An important limitation on the development of information comparable with the above is the fact that the yields of many other plant viruses may be as low as 0.1 to 0.01 per cent of that of tobacco mosaic virus.

In the multiplication of a recently studied crystallizable insect virus, isolable virus can attain a weight approximately 25 per cent of that of its host. This crystallizable virus contains DNA but multiplies in the cytoplasm of the fat-body cells of the larvae of *Tripula paludosa*, the crane fly (Williams and Smith, 1957). This situation evidently presents an interesting opportunity to the biochemist.

However, the multiplication of most animal viruses does not appear to attain such favorable weight ratios. In most instances of viral infection of human tissues virus production appears to represent only a very small proportion of that observed in phage TMV or insect virus infections. For these reasons, the methods of mass analysis indicated above are not generally practicable, since in most cases only a very small proportion of an infected cell can be expected to represent virus-specific products. However, the application of isotopic technics has markedly enlarged the scope of chemical analysis as applied to this problem.

Isotope Technics. In this section will be considered a number of types of experiments which both increase the sensitivity and the specificity of chemical measurement and have assisted in the clarification of the mechanism of virus multiplication.

Some components of interest are synthesized in small amounts, either because their synthesis may have just begun in the course of an experiment, or their role does not require large amounts or their accumulation is not permitted as a result of turnover in virus-infected cells. In some instances there are problems of isolation and estimation which make it difficult to obtain quantitative data. In all of these cases the use of highly radioactive isotopes has proved to be very useful in the following ways.

1. In the analysis of a radioactive component present in small amounts, known amounts of the component can be added in a nonradioactive form to the mixture from which the component is later to be isolated. The radioactivity of the isolated material, corrected for dilution by the added nonradioactive material, will permit the calculation of the initial concentration of the radioactive component [illegible]

1957). This application of the method is the converse of the usual use of the method, as in the amino acid analysis of a protein in which an isotopic amino acid may be added to a protein hydrolysate, where the isotopic compound is diluted by the unlabeled amino acid. In the latter case the dilution of radioactivity by the amino acid whose concentration is to be determined provides an estimate of its initial concentration in the protein hydrolysate.

2. When P^{32} is incorporated into T_2-infected bacteria, it is found that a small amount (1 to 3% of the P of the fraction) is incorporated into the RNA fraction and behaves like RNA. Such an amount could not be detected without the use of isotopes. However, it is difficult to prove that such a small portion of the RNA fraction is indeed RNA and is not an impurity. Degradation of the RNA and fractionation revealed the presence of P^{32}-containing ribose nucleotides which could have been derived only from RNA (Volkin and Astrachan 1957). In this fractionation, the isotopic nucleotides were diluted by the preformed nonradioactive ribose nucleotides of the uninfected cell.

In this experiment, the isotope contents of the 4 ribose nucleotides were found to exist in ratios characteristic of the ratios of the deoxynucleotides of virus DNA and very dissimilar from the ratios of the nucleotides in host RNA, as can be seen in Table 4. Furthermore, it was found that this new synthesis of RNA occurs in a part of the cell readily separable from most of the cell RNA. Such data suggest the following possibilities.

1. Newly synthesized ribose nucleotides may be precursors of deoxyribonucleotides, even as has been suggested in the formation of deoxyribonucleotides in normal bacteria on the basis of isotopic evidence (Lanning and Cohen 1955).

2. The newly synthesized polymeric RNA of the infected cell may play a functional role in the specific synthesis of phage polymers.

the tryptophan analogue inhibits the consequent production of viral DNA In the former instance, infection with damaged virus particles produces unusual metabolic patterns For example, T_2-particles can be prepared which have been burst osmotically to release their DNA and consist essentially of the adsorbable outer shell of the virus (Anderson, 1949; Herriott, 1951) On infection with such phage ghosts, the bacteria stop multiplying, do not produce virus and are severely inhibited in protein synthesis for a considerable period (French and Siminovitch, 1955)

On the other hand, infection of bacteria with ultraviolet irradiated virus inhibits the synthesis of DNA (Cohen, 1948, Cohen and Arbogast, 1950) but does not inhibit initial protein synthesis obtained in normal infection (see Fig 26A) In addition, low molecular precursors of viral DNA accumulate within the infected cell (Cohen, 1951) If the level of ultraviolet irradiation does not prevent multiplicity reactivation in infected cells (Chap 7), it can be shown that viral DNA synthesis is an all-or-none phenomenon requiring a full complement of active viral genetic units (Cohen and Arbogast, 1950).

In analyzing the changes in DNA in T_2-infected cells by chromatographic methods, it has been shown that DNA containing cytosine, i e, host DNA, disappears, and DNA containing viral-specific 5-hydroxymethyl cytosine appears (Hershey et al, 1953; Vidaver and Kozloff, 1957) The ratios of the increments in the purine and pyrimidine bases in infected cells are essentially those observed in virus DNA (Barner and Cohen, 1954); these ratios are different from the ratios of the bases in bacterial DNA In the latter study it was shown that when T_2 infects a thymine-requiring bacterium, the cell is induced to synthesize two pyrimidines—thymine as well as hydroxymethyl cytosine, which the normal bacterium was previously incapable of synthesizing.

In the various experiments relating to T_2-infected cells described above, it was found, as shown in Figure 26A, that the synthesis of various components, including viral specific components such as DNA, occurs at a constant maximal rate. Indeed, the rates at which infected cells incorporate essential elements—phosphorus, nitrogen and carbon—approach the rates of incorporation into normal growing cells. These syntheses are then independent of the number of virus particles present within the infected cell This would suggest that the syntheses are not effected by the tiny infecting virus particle but are rather a function of the relatively invariant enzymatic equipment of the host cell These enzymes continue to make most of the normal building blocks which, instead of entering nucleic acids and proteins, are diverted to the formation of the viral polymers

In some other phage systems, such as T_3 and T_7, the DNA of the bacterial nucleus is entirely degraded and resynthesized into viral DNA without a de novo synthesis of additional DNA, thus, no significant alterations of DNA content can be detected in infected cells (Labaw, 1951, Putnam et al, 1952; Kozloff, 1953)

In some other systems, e g, the T_6-*E coli* system or induced lysogenic systems, other patterns of polymer production may be observed In Figure 26B are presented data on the synthesis of the nucleic acids in lysogenic *B megatherium* after induction with ultraviolet light. The induction results in the mass production of virus and lysis It can be seen that after an initial lag, the production of DNA occurs at a stimulated rate However, unlike the T_2-*E coli* case, there is a marked continuing net synthesis of RNA until the moment of lysis

The amounts of certain plant viruses such as tobacco mosaic virus (TMV) in infected plants can represent very considerable proportions of the total cell protein, TMV may equal as much as 10 per cent of the solids of diseased leaves In these instances a study of the distribution of various protein and nucleic acid fractions may be expected to throw some light on events during multiplication A series of cyclic changes has been observed in soluble protein, insoluble protein, and RNA in infected and uninfected cells, and differences between the contents of these fractions have been related to virus synthesis (Basler and Commoner, 1956). Thus, virus biosynthesis is associated with a net increase in plant proteins (Commoner et al, 1953) and seems to be most closely associated with a buffer-insoluble cell component. After infection there is a synthesis of new RNA, and this material

conditions For example, cells labeled in cytosine with C^{14} and infected in unlabeled media could be observed to lose DNA-cytosine-C^{14} and accumulate HMC-C^{14} (Hershey et al, 1954) In other experiments it was also shown that bacterial RNA contributed to the formation of virus DNA Thus, if cells grown in the presence of C^{14}-glucose are permitted to grow briefly in the absence of isotope to exhaust intermediary metabolites, and then infected in C^{12}-glucose, it is found that the total amount of radioactivity in intracellular DNA-bases increases, whereas the label in RNA decreases slightly (10 to 20%) but significantly.

A modification of this type of experiment, i e, shifting from labeled to unlabeled metabolites, has been used extensively to map metabolic pathways The technic attempts to assess the effects of simultaneously offering two possible sources of metabolites, only one of which is labeled If the labeled compound is indeed the precursor, the newly made substance will contain its radioactive atoms If the unlabeled component offered will enter the metabolic path to provide unlabeled atoms for the synthesis of the component investigated, such an unlabeled source will compete as a source of atoms and will reduce the number of radioactive atoms incorporated per unit synthesized Such a technic is known as "isotope competition" (Roberts et al, 1955) A typical experiment is given in Table 5

It can be seen that fed adenosine dilutes isotope in the formation of bacterial adenine and guanine but only slightly of bacterial ribose On the other hand, C^{12}-pyrimidine nucleosides do not seriously affect isotope incorporation from C^{14}-glucose into purines but do provide competitive unlabeled ribose for RNA synthesis

Many comparable competition experiments have been done with normal and virus-infected bacteria (Siminovitch and Graham, 1955, Hershey et al, 1954). For example, it has been shown that if C^{14}-uracil is fed to a uracil-requiring strain of *E coli*, the organism contains the C^{14}-pyrimidine in its nucleic acid pyrimidines Simultaneously offered C^{12}-cytosine deoxyriboside will dilute the isotope content of newly synthesized thymine However, no hydroxymethylpyrimidine offered at the free base or nucleoside level, including hydroxymethylcytosine deoxyriboside, will compete with C^{14}-uracil in entering infected cells to become T_2 or T_6 pyrimidines (Cohen et al, 1957) These compounds do penetrate infected cells and therefore are excluded as possible intermediates in the biosynthesis of viral pyrimidines

Such an experiment does not exclude pyrimidine nucleotides as intermediates However it is not possible to feed such a nucleotide in hopes of its entrance into a normal metabolic pathway, since experiments with P^{32}-labeled nucleotides have indicated the release of the P^{32} and its redistribution to other nucleotides (Lesley and Graham, 1956). In this case, one must seek a new method of increasing permeability to such compounds or study nucleotide metabolism in cell-free extracts

As is considered below, a number of investigators have undertaken to label the infecting virus particles and to determine the fate of parental viral substance In this way, it was found that some of the phosphorus atoms of the parental nucleic acid of a T-even phage particle appeared in the progeny It can be asked if this transferred P derives from intact viral nucleic acid or represents the re-utilization of P from degraded nucleic acid Hershey et al (1954) performed competition experiments to approach this problem These workers prepared uniformly labeled C^{14}-glucose The isotopic phage was used to infect unlabeled bacteria in unlabeled medium and the DNA bases of the progeny isolated from

NUCLEOTIDES	PER CENT DISTRIBUTION OF BASES IN *E coli* RNA	PER CENT DISTRIBUTION OF P^{32} IN T_2-*E coli* RNA	PER CENT DISTRIBUTION OF BASES IN T_2 DNA
Cytosine *	23	18	17
Guanine	31	22	18
Uracil *	23	30	32 5
Adenine	23	30	32 5

* Virus DNA contains thymine, instead of uracil, and cytosine is replaced by 5-hydroxymethyl cytosine.

Although neither hypothesis is rigorously proved, it is possible that both are correct. When P^{32} ... for ... radi... P^{32} ... DNA continues to incorporate P^{32} while the content of this isotope in RNA falls reciprocally Thus, the P^{32} ribose nucleotides appear to be precursors of DNA deoxyribotides at some level of organic phosphorus compounds It is not known whether these levels of precursor organization are nucleotides or polynucleotides The process of making isotope available to infected cells for brief intervals is termed a "pulse" experiment and will be referred to again below

Precursor relations of virus components have been examined by 3 main types of isotope experiments. In these, a labeled compound may be present (1) in the medium at various ... in the ... (3) in ... multipl... involves continuity of viral substance These experiments were first developed in phage systems and have since begun to be extended to ...

In ... source ... a T-e... eration ... labeled cells, i e, cells grown in P^{32}-containing media but infected in unlabeled media or conversely infected in unlabeled cells in a medium containing P^{32}. Virus was isolated, and the radioactivity of the P was determined as compared with the P of labeled host or labeled medium, respectively. It was found that from 70 to 80 per cent of the P of the virus was derived from the exogenous P of the medium

By means of a selective labeling of the host nucleic acids with nucleic acid components, i e, with C^{14}-adenine and thymine (Kozloff, 1953), it was shown that the main source of the host contribution, i e., 20 to 30 per cent of the T_6r^+ nucleic acid, was host DNA By infecting cells, previously labeled in their pyrimidines through growth in C^{14}-orotic acid, and liberating and isolating virus at various stages ... This was taken to mean that components of the host nucleic acid do not fulfill a role as genetic determinants within the T-even phages, a fact substantiated by the subsequent discovery that phage nucleic acid is devoid of cytosine, a base found in host DNA (Wyatt and Cohen, 1953)

As summarized by Kozloff (1953), it has been shown in studies of the T-odd phages by these technics that from 60 to 90 per cent of the viral DNA-P and DNA-N came from the host cells, which show little or no synthesis of DNA after infection

In an extension of these experiments, Stent and Maaloe (1953) and Labaw (1953) introduced the method of rapidly adding or diluting isotope at intermediate stages of the multiplication cycle, i e, the "pulse" experiment, and observing the effect on the radioactivity of the liberated infectious phage By this technic the former workers showed that the average time spent by phosphorus atoms between assimilation and incorporation into the intact phage was about 14 minutes. In this process, however, newly assimilated P mixes at some metabolic level with P derived from host DNA

In further refinements it was realized that intermediate products of the infected cells rather than completed liberated phage could also be determined under various labeling

conditions. For example, cells labeled in cytosine with C^{14} and infected in unlabeled media could be observed to lose DNA-cytosine-C^{14} and accumulate HMC-C^{14} (Hershey et al, 1954). In other experiments it was also shown that bacterial RNA contributed to the formation of virus DNA. Thus, if cells grown in the presence of C^{14}-glucose are permitted to grow briefly in the absence of isotope to exhaust intermediary metabolites, and then infected in C^{12}-glucose, it is found that the total amount of radioactivity in intracellular DNA-bases increases, whereas the label in RNA decreases slightly (10 to 20%) but significantly

A modification of this type of experiment, i e, shifting from labeled to unlabeled metabolites, has been used extensively to map metabolic pathways The technic attempts to assess the effects of simultaneously offering two possible sources of metabolites, only one of which is labeled If the labeled compound is indeed the precursor, the newly made substance will contain its radioactive atoms If the unlabeled component offered will enter the metabolic path to provide unlabeled atoms for the synthesis of the component investigated, such an unlabeled source will compete as a source of atoms and will reduce the number of radioactive atoms incorporated per unit synthesized Such a technic is known as "isotope competition" (Roberts et al, 1955) A typical experiment is given in Table 5

It can be seen that fed adenosine dilutes isotope in the formation of bacterial adenine and guanine but only slightly of bacterial ribose On the other hand, C^{12}-pyrimidine nucleosides do not seriously affect isotope incorporation from C^{14}-glucose into purines but do provide competitive unlabeled ribose for RNA synthesis

Many comparable competition experiments have been done with normal and virus-infected bacteria (Siminovitch and Graham, 1955, Hershey et al, 1954) For example, it has been shown that if C^{14}-uracil is fed to a uracil-requiring strain of *E coli*, the organism contains the C^{14}-pyrimidine in its nucleic acid pyrimidines Simultaneously offered C^{12}-cytosine deoxyriboside will dilute the isotope content of newly synthesized thymine However, no hydroxymethylpyrimidine offered at the free base or nucleoside level, including hydroxymethylcytosine deoxyriboside, will compete with C^{14}-uracil in entering infected cells to become T_2 or T_4 pyrimidines (Cohen et al, 1957) These compounds do penetrate infected cells and therefore are excluded as possible intermediates in the biosynthesis of viral pyrimidines

Such an experiment does not exclude pyrimidine nucleotides as intermediates However it is not possible to feed such a nucleotide in hopes of its entrance into a normal metabolic pathway, since experiments with P^{32}-labeled nucleotides have indicated the release of the P^{32} and its redistribution to other nucleotides (Lesley and Graham, 1956) In this case, one must seek a new method of increasing permeability to such compounds or *study nucleotide metabolism in cell-free extracts*

resulting lysates were analyzed for radioactivity In parallel experiments the unlabeled compounds—adenine, guanine and thymidine—were added in an attempt to compete with the labeled bases in the infecting phage DNA. No change in the distribution of isotope was obtained in any of these competition experiments as contrasted with the control. It would appear that parental DNA is not broken down to a level at which the competition of exogenous derivatives could occur, and it was concluded that DNA is transferred in large pieces which might conceivably be genetically functional.

Isotopic technics enable the investigator to study the fate of the major components of a system of infected cells, i e , virus, cell, or medium. Although the examples given above have been derived mainly from questions on the role, the origin and the fate of nucleic acids in phage systems, these kinds of experiments can also be applied to other cell systems and to problems involving types of other metabolism, e g , protein In the study of protein metabolism, an isotope of sulfur, S^{35}, an element not found in nucleic acid, has been particularly useful, as have C^{14}-amino acids and the stable isotope, N^{15} P^{32} has not yet been of interest in the study of protein metabolism in infected cells in the absence of knowledge of protein-bound P in viruses or of its role in many metabolic events

In animal virus systems it has been difficult until recently to perform clearcut isotope experiments Many experiments have been done since 1949 on P or C isotope uptake in intact infected animals or in infected eggs. The early history of such experiments using influenza virus, vaccinia virus, Theiler's virus, etc., has been summarized by Blank (1956) In such experiments it has been customary to note a slight increase in isotope uptake in animal, egg, or one or another fraction on infection as contrasted with control Occasionally, the incorporation into virus has been studied as well. For the most part, however, the biologic systems employed have not been used to permit single cycles of multiplication and have precluded extensive incorporation into virus or into components which might be purified sufficiently to warrant designation as viral components.

However, isotope experiments have begun

the effect of poliomyelitis infection on P^{32} utilization in the HeLa cell and have observed an accelerated uptake into nucleic acid and phospholipid fractions of such cultures

In the earliest experiments with minced one-day-old mouse brain infected with Theilers GVII virus, P^{32} uptake was stimulated in the RNA fraction but not in DNA (Rafelson et al , 1949). Such a result may be taken to suggest that this virus is probably an RNA virus, as is human poliomyelitis virus. Subsequently, it was determined that P^{32} incorporation into the nucleic acid of the smallest particulate fraction of mouse brain was stimulated maximally (Moldave, 1954). Thus, such experiments as unsatisfactory as they are, nevertheless permit a beginning in the orientation of biochemical thinking concerning a virus difficult to isolate and purify When labeled virus has been isolated, as in studies with influenza virus, it has been used to study viral adsorption (Liu, 1956), viral composition (Graham, 1950, Hoyle et al , 1954, Franklin et al., 1957) and viral penetration (Hoyle and Frisch-Niggemeyer, 1955, Hoyle and Finter, 1957)

Most isotopic studies of plant virus multiplication, i e , the biosynthesis of tobacco mosaic virus, have used the stable isotope, N^{15}, to analyze the interrelations of normal tobacco protein, the amino acid pool and virus (Meneghini and Delwiche, 1951, Commoner et al , 1953)

The Synthesis of Incomplete Influenza Virus. It was shown first in the multiplication of turnip yellow mosaic virus that infected plants elaborated both an infectious spherical nucleoprotein and a noninfectious spherical protein shell which appeared to be identical with the virus except for the lack of the internal core of virus RNA (Chap. 2). Studies of Commoner et al. (1953) suggest that the lack of availability of RNA components such as uracil may indeed limit tobacco mosaic virus production It has been supposed that virus infection may lead to the independent synthesis of RNA and protein units which eventually assemble to form the complete nucleoprotein or in the absence of sufficient nucleic acid organize protein particles, i e , incomplete virus.

Under certain conditions of infection of chick embryos with influenza virus, the yields contain a high proportion of noninfectious hemagglutinins in addition to infectious virus particles On an additional cycle of infection

with such a harvest, the progeny are almost entirely devoid of infectivity. Such noninfectious hemagglutinating particles have been termed "incomplete," and indeed the study of Ada and Perry (1955) has revealed that the RNA content of a population of purified virus from infected allantoic fluids is proportional to the logarithm of the ratio of infectious to hemagglutinating particles. Thus, noninfectious particles lack a complete complement of RNA, are structurally less firm in electron micrography, and indeed appear to have a lower sedimentation coefficient than do preparations of highly infectious virus. In confirmation of these results, Henle (1956) has described experiments on P^{32} uptake in the production of incomplete influenza virus. He reports that compared with fully infectious influenza virus such isolated "incomplete" particles contain a lower percentage of the total P^{32} in the nucleic acid and perhaps a relatively higher percentage in the lipid fraction. The results to date are consistent with the view that influenza virus consists of small hemagglutinating particles plus a nucleoprotein component enclosed in a lipid envelope, that, as suggested by Hoyle (1952), the nucleoprotein element is of particular significance in initiating multiplication, and that in the formation of incomplete virus there is just not enough complete nucleoprotein to go around. In addition, the point may be made that the hemagglutinin must be on the surface of the virus particle. The structural and isotopic work on fowl plague virus, which is closely related in morphology, composition and multiplication to influenza virus, also appears to substantiate this general picture (Wecker and Schafer, 1956, Schafer, 1957). It is evident that structural and isotopic studies are beginning to clarify the multiplication of influenza virus, however, the point may be made that these studies must also be set within a kinetic analysis of the sequence and the mode of formation of all the various virus-specific units.

Energy Requirements for Virus Multiplication

It had been postulated some years ago that the intracellular multiplication of viruses might resemble an autocatalytic conversion:

1. Trypsinogen $\xrightarrow{\text{trypsin}}$ trypsin
2. Virus precursor $\xrightarrow{\text{virus}}$ virus

in which the virus precursor would be a large organized preformed nucleoprotein. The data presented above already indicate that this model does not typify the multiplication of any known virus. The net synthesis of the complex substances from simple nutrients indicated a far more complex array of metabolic steps. Such syntheses evidently have energetic requirements of a far different quality and magnitude than that represented by the hydrolytic conversion of the precursor trypsinogen to trypsin. The synthesis of virus polymers requires a considerable expenditure of energy, at least in raising intermediary metabolites to the level of producing the activated amino acids and nucleotides which can participate in protein and nucleic acid synthesis. Such activated compounds contain high energy bonds which embody a sufficiently high group transfer potential to permit the addition of activated amino acids to amino acids to extend peptide chains and the addition of activated nucleotides to extend polynucleotide chains as well as to participate in a multitude of reactions involving the activation of other intermediary metabolites.

It is evident then that virus multiplication must utilize the major sources of energy metabolism available to normal cells. In anaerobic and aerobic cells this involves the development of oxidative phosphorylation via hydrogen transport. Other mechanisms are also available whereby oxidation-reduction is tied more directly to the development of high energy bonds. Thus, in anaerobic glycolysis the conversion of 1 mole of glucose to 2 moles of lactic acid occurs with the net production of 2 moles of adenosine triphosphate (ATP). In the oxidation of pyruvate, the free energy evolved in the conversion of a 2-carbon fragment at the oxidation level of acetaldehyde to that of acetate may be conserved in the formation of a thioester of acetate, which can then be transferred or exchanged to form other high energy bonds. Since enzymes controlling oxidation-reduction are apparently not present in the viruses, we are concerned in the main then with host systems of metabolism. It would not be anticipated that these systems would be seriously affected during active

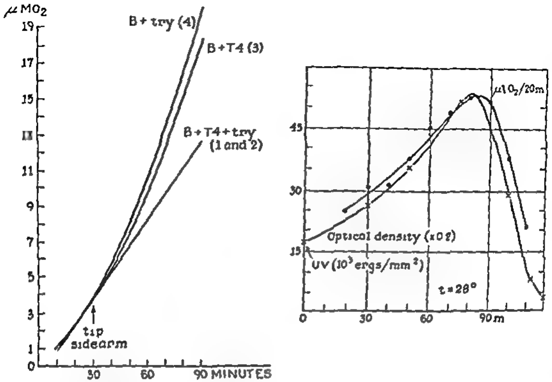

FIG 27 (A, *Left*) The effect of T4r+ virus adsorption on the rate of O_2 consumption of culture of *E coli* strain B in lactate medium Try-tryptophan, the adsorption cofactor for T4 (Cohen, S. S., and Anderson, T. F, 1946, Chemical studies on host-virus interaction. I The effect of bacteriophage adsorption on the multiplication of its host, *Escherichia coli* B J. Exper Med *84*, 511-523) (B, *Right*) Measurement of rate of respiration after induction of *B. megatherium 899* by ultraviolet light (Siminovitch, L., 1953, Biochemical modifications of the bacterial host during bacteriophage development, Ann Inst Pasteur *84*, 265-273)

polymer and virus synthesis, although the diversion of metabolic products from maintenance and repair mechanisms may eventually result in cell damage Conversely, it can be expected that the inhibition of major routes of energy metabolism will seriously affect the course of virus production. In general, these expectations are realized in most systems examined, although some few exceptions have been reported

It was first observed with *E coli* infected with T_2 or T_4 phages that infected cells maintained the rate of O_2 consumption or respiratory quotient obtained with growing cells immediately prior to infection (Cohen and Anderson, 1946). However, although uninfected cells exhibited the normal increase of respiration as a result of growth and division and the biosynthesis of respiratory systems, T_2 or T_4 infected cells did not increase their O_2 consumption, since normal growth and the synthesis of respiratory enzymes ceased. These data are represented in Figure 27A

Similar results have been obtained with a number of other virulent phages infecting *Pseudomonas aeruginosa* and T_5 infecting *E coli* (Holliman et al, 1952) On the other hand, following induction of lysogenic *B megatherium*, in which growth and RNA synthesis continue until lysis, the rate of O_2 consumption increases as in Figure 27B (Siminovitch, 1953)

Phages are known for anaerobic organisms, and a number of investigators have compared aerobic and anaerobic virus production in facultative organisms Fowler (1950) has studied this for T_2 infecting *E coli* and has shown that *E coli*, adapted to anerobic growth on glucose, is capable of producing normal amounts of virus Since it is well known that

high-energy compounds can be developed during anaerobic growth, it should not be surprising that polymer and virus synthesis may continue under these conditions

However, if the bacteria had not been adapted to anaerobic conditions prior to infection, virus production did not occur Infection by T_2 of aerobic *E coli* in the absence of O_2 resulted in lysis without virus production (Cohen, 1949). As summarized by Adams (1954), this type of lysis is related to the phage used and the medium in which the organism is grown The effect may be expected to be maximal in a lactate medium where it was first observed, in view of the fact that *E. coli* infected with T_2 or T_7 accumulate pyruvate, indicating a decreased ability to handle this substrate on infection (Spizizen, 1957b) In the T_2-*E coli* system the elimination of an energy source and the provocation of lysis can be effected with inhibitors such as cyanide (Cohen, 1949) and 2,4-dinitrophenol (Heagy, 1950) The penetration of phage DNA requires the puncturing of the cell wall, resulting in an increased leakage of metabolites from infected cells, which is repaired in later stages of the multiplication cycle (Puck and Lee, 1954, 1955) The lysis observed to occur on the elimination of an energy supply or resulting from a high multiplicity of infection (lysis from without) has been suggested to arise from the failure of the repair mechanism to operate in infected cells, a mechanism which may be presumed to involve extensive protein synthesis

Many studies have been made comparing respiration in healthy and virus-infected plants In one of the most careful comparisons of healthy and mosaic-diseased tobacco plants from the time of inoculation, it was concluded that the respiration rates are essentially similar until the disease became systemic (Gladstone, 1942). Numerous reports have appeared of increased and decreased respiration rates in infected plants, in many instances increased respirations have been interpreted as reflecting translocations of utilizable substrates (Wynd, 1943, Bawden, 1950)

In animal virus systems most investigators have failed to observe inhibition of respiration of a host tissue during propagation of virus Such results have been obtained for the polyhedral disease of silkworms (Gratia et al, 1945), and infections with viruses of murine encephalomyelitis (Pearson and Winzler, 1949) Newcastle disease and Western equine encephalitis (McLimans et al, 1950), influenza, Ackermann, 1951, Tamm, 1956), feline pneumonitis (Moulder and Weiss, 1951) and vaccinia virus (Overman and Tamm, 1957) Of course, after cytopathology develops, a decrease in respiratory rate is common, as in herpetic infection in chick liver and heart, which results in mitochondrial destruction (Ackermann and Kurtz, 1952), or late in vaccinial multiplication in chorio-allantoic membranes (Overman and Tamm, 1957)

In a number of infections, e g, feline pneumonitis (Moulder and Weiss, 1951), murine encephalomyelitis (Pearson and Winzler, 1949), the anaerobic glycolysis of infected tissue is stated to be unchanged However, in a variety of instances, this function is reported to be altered In the studies of Smith and Kun (1954) extracts with infections of myxoma, fibroma, herpes simplex, rous sarcoma, swine influenza, Newcastle disease and rabies, the rates of production and O_2 consumption of the chorio-allantois were unchanged as contrasted with the normal tissue while the rate at which extracts of infected membranes produced acid from hexose diphosphate (a measure of anaerobic glycolysis) was increased markedly Sterile inflammation of the membrane did not produce this result. A stimulatory effect on anaerobic and aerobic glycolysis by poliovirus infection of monkey kidney cells in tissue culture has also been observed (Levy and Baron, 1957) As will be noted below, evidence has been obtained for an increase in the use of a pathway of anaerobic glycolysis in T_2-infected bacteria

Although many workers have reported a diminution of virus production in anaerobic conditions, it has been observed recently that poliovirus will reproduce similarly in the HeLa cell in anaerobic as well as aerobic conditions (Gifford and Syverton, 1957) The HeLa cell has a normally high rate of aerobic glycolysis and may be thought of as having a most active functioning anaerobic Embden-Meyerhof pathway even in aerobic conditions. Thus, it may be adapted to anaerobiosis before infection, unlike some other systems studied

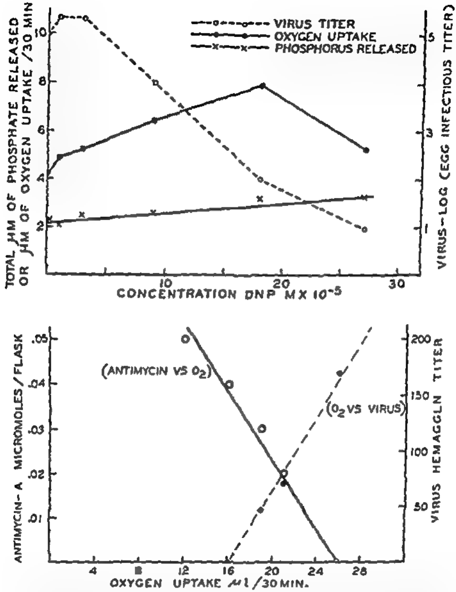

FIG. 28. (A, *Top*) Uncoupling effect of dinitrophenol (DNP) on propagation of influenza virus in the chorio-allantoic membrane of the chick embryo (Ackermann, W W, and Johnson, R. H., 1953, Some energy rela- [illegible]

Virus and Rickettsial Infections, pp 101-110, New York, Blakiston)

It may be noted that many workers have reported phenomena suggestive of an increase in the permeability of infected cells in a manner analogous to that described for phage systems In the absence of a rapid repair mechanism, anaerobiosis may reduce energy supply and merely augment this effect, as it does in phage systems The inhibition of anaerobic glycolysis by leukocytes as a result of treatment with the influenza viruses or by the receptor-destroying enzyme of *Vibrio cholerae* (Fisher and Ginsberg, 1956) has been interpreted to suggest that a permeability increase with loss of essential phosphorylated intermediates may have been responsible for the observed inhibition It is noteworthy that such abused leukocytes, when supplied with phosphorylated intermediates, such as fructose-6-phosphate, were able to glycolyse and phagocytize, in contrast with their loss of these functions with glucose as exogenous substrate.

Inhibitors have been useful in demonstrating energetic requirements for virus multiplication, and particularly the contribution to energy requirements which may stem from oxidative systems As given in Figure 28A, uncoupling of oxidative phosphorylation from respiration by dinitrophenol reduces influenza virus yield in chorio-allantois in proportion to the increase in O_2 consumption which this agent stimulates (Ackermann and Johnson, 1953, Eaton, 1952) Dinitrophenol also stimulates the ATPase of the membrane, resulting in the formation of inorganic phosphate in the medium Sodium malonate (Ackermann, 1951) and sodium fluoroacetate (Mogabgab and Horsfall, 1952), which also inhibit influenza virus production, prevent the normal functioning of the tricarboxylic acid cycle, which in oxidizing acetate both facilitates oxidative phosphorylation and supplies important intermediates for protein synthesis Other inhibitory agents, such as antimycin A, which interferes with electron transport (Ackermann, 1951), also prevent influenza virus production, as in Figure 28B Similar agents include arsenite, cyanide, azide, etc, which inhibit the multiplication of phage (Dolby, 1955), vaccinia virus (Thompson, 1947), and feline pneumonitis virus (Moulder et al, 1953)

It must be emphasized that although the use of the inhibitors and the exploration of these peripheral areas of energy metabolism have established the gross generalities stated at the beginning of this section, the core of the biochemical problem cannot be approached by these primitive technics This central problem may be stated to be that of the nature of the energetic coupling involved in the synthesis of the viral polymers It is not known whether these synthetic reactions differ in any significant respect from the synthesis of comparable host polymers, whose mechanisms of synthesis are also still unknown

Enzyme Changes in Virus-Infected Cells

Direct and indirect approaches have been employed in attempting to seek or assess changes in the enzymatic activities of virus-infected cells It is possible to disrupt cells and assay directly for enzyme content As noted earlier, to be interpretable any observed changes in enzyme content require a knowledge of both the stage of infection analyzed and the percentage of infected cells among the cells studied A second type of analysis has explored the rate at which infected cells use given substrates, incorporate such substrates in fractions of infected cells or accumulate or excrete various metabolic products or intermediates A number of instances have already been recorded of this type of study, as in the analysis of respiration or glycolysis, or the incorporation of P^{32} in nucleic acids, etc It is immediately evident that the extrapolation from an observation of substrate utilization by intact cells to a conclusion of a change in enzyme content or activity must be approached with caution, since a change in the rate of utilization may arise from permeability changes, a shift from one biosynthetic pathway to another, structural alteration, etc

To exemplify this point, we may refer to the fact of pyruvate accumulation in virus-infected bacteria (Spizizen, 1957) The additional observation was made that various compounds, probably including cocarboxylase, which are capable of stimulating pyruvate utilization, leak from such infected cells As indicated above, such a permeability change could account for the inhibition of glycolysis by leukocytes treated with influenza virus

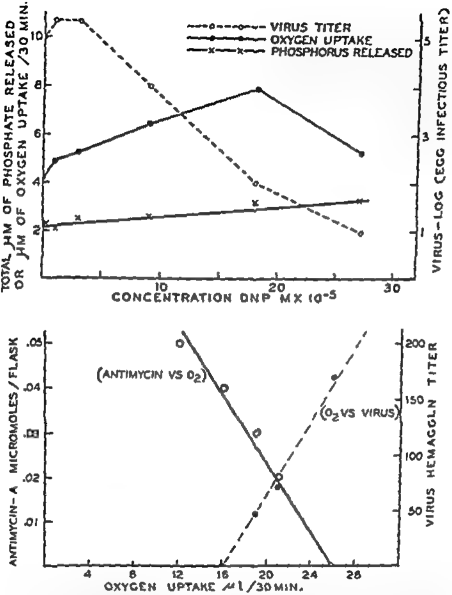

FIG 28. (A, *Top*) Uncoupling effect of dinitrophenol (DNP) on propagation of influenza virus in the chorio-allantoic membrane of the chick embryo (Ackermann, W W, and Johnson, R. B., 1953, Some energy relations in a host-virus system, J. Exper Med *97*, 315-322) (B, *Bottom*) Relationships of antimycin-A concentration on oxygen uptake and influenza virus propagation in chorio-allantoic membrane (Ackermann, W. W.

drogenases of glucose-6-phosphate and 6-phosphogluconate, were present in amounts equivalent to those of the normal cells, i e, an amount capable of handling 40 per cent of the total glucose utilized (Scott and Cohen, 1953; Scott, 1956). Another type of test made use of the physiologic irreversibility of the formation of phosphogluconate. When *E. coli* is adapted to gluconate, the bacteria form a gluconokinase which converts gluconate to 6-phosphogluconate, as in the diagram on page 78 (Cohen, 1951). When such adapted cells are infected by T_2, in the presence of gluconate-1-C^{14}, essentially all of the isotope appears in CO_2 as a result of the oxidative decarboxylation of 6-phosphogluconate. Nevertheless, the infected cell elaborates virus and virus DNA (Cohen and Roth, 1953) Thus, at least all but one of the enzymes of the phosphogluconate pathway are not inhibited and are capable of functioning in infected cells, if compelled to by the appropriate choice of substrate; however, these enzymes tend not to be used if glucose is offered The glucose-6-phosphate dehydrogenase, not tested by this method, had been shown to be present by direct assay, and by earlier isotope analyses It was concluded that virus infection appears to inhibit the use of the phosphogluconate pathway by controlling other levels of metabolism

Thus, although O_2 consumption during utilization of glucose showed no apparent change, this constancy masked a shift in balance between alternative paths of carbohydrate metabolism This technic has not yet been extended to other viral systems, although now being applied widely in the analysis of carbohydrate metabolism. Recently, an increased use of the phosphogluconate pathway has been reported for rust-infected wheat (Shaw and Samborski, 1957)

Other functions in such infected bacteria show more evident changes in the utilization of given substrates Thus, certain nucleic acid derivatives such as adenine, adenosine, and thymidine disappeared at greater rates in infected cultures which, nevertheless, deaminated cytosine derivatives or cleaved nucleosides more slowly (Friedman and Gots, 1953) On the other hand, a number of different enzymes in extracts of infected cells, e g, apyrase, ribonuclease, etc, are said to be present to a similar degree in infected and normal cells (Pardee and Kunkee, 1952)

A very interesting change in the deoxyribonuclease content of infected *E. coli* has been observed (Pardee and Williams, 1953; Kozloff, 1953) This is an increase in the enzyme which has been correlated with the destruction of a small fraction of DNAase-inhibitory RNA However, although this increase has been described earlier as an activation, it may be a de novo formation of enzyme, since the increase is specific for T-even phages, and occurs only when phage DNA is injected and an energy source is supplied (Kunkee and Pardee, 1956).

It was shown very early that bacteria infected by certain virulent phages could not be induced to use a new carbon source (Monod and Wollman, 1947), and it was assumed that this exclusion of induced biosynthesis was a reflection of the priority for the synthesis of phage polymers which infection imposed on the cell This priority system broke down in certain lysogenic systems (Jacob, 1953) which could adapt to new substrates after induction Evidence is beginning to accumulate to suggest that the exclusion of enzyme synthesis may not hold entirely in virulent systems either Indeed, it now appears that the inhibition of synthesis of protein or of inducible enzymes in T_2 systems is an early effect of infection, unrelated to the phage polymer biosynthesis directed by injected DNA, since such an inhibition can be produced by attachment of T_2 ghosts which arrest bacterial multiplication and biosynthesis (French and Siminovitch, 1955)

In the phage infection of certain strains of *Klebsiella pneumoniae*, an enzyme is elaborated which is partially attached to the virus and hydrolyzes the capsular polysaccharide of the bacterium (Park, 1956) Comparable enzymes had been found earlier in other phage-bacterial systems, as summarized by Adams and Park (1956), and could not be detected in uninfected cells or culture media In these instances, it was not shown whether infection merely uncovered an inhibition; indeed, the new enzyme might have arisen as a result of the liberation of inducing products in the initial penetration of the capsule

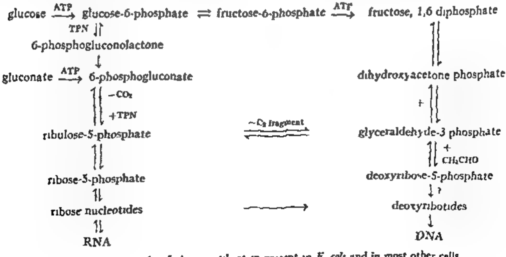
In the case of the formation of 5-hydroxymethyl deoxycytidylic acid in *E. coli* in-

(Fisher and Ginsberg, 1956). A variety of changes in substrate utilization by chorioallantois infected with influenza virus have been recorded. Pyruvate, a difficulty penetrable substrate, is taken up at a slightly greater rate than in normal tissue (Wielgosz, 1957), as are N^{15}-alanine, C^{14}-glycine, or P^{32}-phosphate (Huttin et al, 1954, van den Ende, 1950) The latter results were shown to be due mainly, if not entirely, to increased permeability in the membrane, and these effects of infection could be simulated by treatment of normal tissue with hyaluronidase

A wide variety of metabolic changes has been observed in phage-infected cells in which analyses at the enzymatic level have also been attempted. Of these studies of infected bacteria, one of the most interesting cases began with the demonstration of no apparent metabolic change at all. It has been noted that the rate of O_2 consumption and respiratory quotient does not change after infection with a T-even phage However, the pattern of synthesis, particularly with respect to nucleic acid, changed markedly after infection. It was shown that in *E. coli*, ribose arose predominantly from the oxidative phosphogluconate pathway (Lanning and Cohen, 1954), one of two alternative pathways of glucose utilization, of which the other is the anaerobic Embden-Meyerhof pathway A simplified relation of these alternative routes is given in the accompanying diagrams; these routes and others exist in most bacteria, plants and animals

Since net ribose synthesis in infected *E coli* was sharply reduced, it could be asked if the use of the phosphogluconate pathway had been similarly reduced. In the metabolism of glucose via this pathway, the first carbon, C_1, of glucose is selectively oxidized to CO_2, whereas in the metabolism of glucose via the Embden-Meyerhof pathway this carbon atom ends as the methyl carbon of pyruvate and lactate, a position in which its oxidation to CO_2 is minimal (Cohen, 1954, Wood, 1955). If glucose-1-C^{14} were offered growing bacteria, it was found that 22 per cent of the total glucose carbon used appeared as CO_2, but that 38 per cent of the C_1 appeared in this form During growth then the phosphogluconate pathway could account for a maximum of 38 per cent and a minimum of 16 per cent of the glucose used During infection, although total CO_2 production was unchanged, the $C^{14}O_2$ was sharply reduced, indicating a reduction in the utilization of the phosphogluconate pathway and a shift of some glucose to another pathway of glucose metabolism (Cohen, 1951b). It has been shown most recently that under such conditions a far greater proportion of the ribose produced in infected cells also arises from pathways other than the phosphogluconate pathway (Loeb and Cohen, 1958 in preparation).

Did virus infection directly inhibit enzymes of the phosphogluconate pathway? Disruption of infected cells revealed that the two initial enzymes of this pathway, the dehy-



Two alternative paths of glucose utilization present in *E coli* and in most other cells

have not been clearly resolved for any virus, their analysis has begun

A most important approach has involved the use of isotopically labeled virus Although most of the significant studies in this area have been performed in phage systems, similar studies have begun with animal virus systems The earliest experiments employed virus labeled in protein or nucleic acid to determine the general patterns of utilization of viral substance. Using P^{32}-labeled T_6, it was found first that from 30 to 40 per cent of the isotope subsequently appeared in material identified as progeny phage (Putnam and Kozloff, 1950). This result was generally confirmed with N^{15} as well as using T-even and T-odd phages, as summarized by Kozloff (1953), with the additional observation that significant amounts of DNA-P^{32} are rendered acid-soluble and hence are of low molecular weight (Lesley et al 1951) It was demonstrated that such a degradation is stimulated markedly under conditions of multiple infection and superinfection with the T-even phages and appears to be related to the "activation" of deoxyribonuclease occurring in infection with T-even phages (French et al, 1952, Graham, 1953) Very little degradation of viral protein occurred under comparable conditions (Kozloff, 1952a) and, as French (1954) subsequently showed, only 2 per cent of the lysine-C^{14} in labeled parent appeared in the progeny Thus, significant amounts of only viral nucleic acid appeared in the progeny.

Watson and Maaløe (1953), controlling phage adsorption to minimize superinfection breakdown and reducing readsorption of progeny to debris, raised the P^{32} or purine base transfer figures to about 50 per cent for T-odd and T-even phages This transferred substance was found predominantly in the early formed phages It was also found, as reported earlier by Kozloff (1952b) as well, that damaged or genetically different phages incapable of participating in multiplication nevertheless contributed their phage DNA to progeny as well In an earlier experiment (Maaløe and Watson, 1951), it was shown that progeny containing 30 per cent of their P^{32} from parental transfer also transferred only 30 per cent of their P^{32} to a second generation and it was concluded that the transfer of parental virus P and N was largely independent of genetically active units (Maaløe and Watson, 1951; Kozloff, 1952b).

In the experiment of Hershey and Chase (1952) on the selective penetration of phage DNA into the infected bacterium, the basis of the exclusion of viral protein was clearly shown At least 85 per cent of the viral protein which may be selectively labeled with S^{35} existed in the protein outer coat of the T-even phages S^{35} or P^{32} T_2 was adsorbed to *E coli*, and the infected cells were suspended in a medium low in electrolytes and spun in a Waring blendor, Strippable S^{35} was separated from the infected cells, still competent to yield phage, by low-speed centrifugation It was found that 80 per cent of viral S^{35} and amino acids and only 20 per cent of the DNA were in the supernatant fluid. Most viral protein then was in the disposable extracellular syringe while the viral DNA was injected and became intracellular Hershey (1955) has since found that up to 3 per cent of the viral protein is injected into the bacterium with the DNA, its function is unknown, and it is not transferred to the protein of viral progeny.

Similar phenomena of the attachment of the protein to the outer cell wall and the injection of DNA have been shown for T_5 (Lanni, 1954) and T_1 (Christensen and Tolmach, 1955) In the former instance, the attachment of phage protein and its detachment by the blending technic were followed by testing for the specific complement-fixing antigens of T_5

In general terms and as is discussed in greater detail in Chapter 7, only the phage DNA appears to transfer genetic information to the infected bacterium and, in the virulent systems studied, this code or set of codes replaces those of the bacterium whose nuclei are destroyed following infection In comparable transfer experiments with a lysogenic system of the temperate phage P_1 infecting Shigella dysenteriae (Goodgal, 1956), it was shown that almost all of the phage DNA is transferred to the bacterium Furthermore, the P^{32} was conserved to form a stable bacterial DNA component in the now lysogenic organism and was retained in subsequent divisions. In this instance, since multiple infection permitted the retention of the DNA of

fected by the T-even phages, the essential hydroxymethylating enzyme is not in uninfected bacteria or in phage, appears only on T-even phage infection and is associated with protein synthesis after the injection of viral DNA (Flaks and Cohen, 1957, 1958). Present data suggest that fragments of phage DNA containing the unique pyrimidine may induce the synthesis of the essential hydroxymethylase.

Reference has been made to respiration in infected tobacco plants and the changes appearing with increased translocation of substrates within the plants. Many metabolic alterations are known in virus-infected plants, these encompass the appearance of new products, increased amounts of old substances, and marked shifts in the content of certain enzymes and systems often found associated with chloroplasts (Wynd, 1942, 1943, Bawden, 1950). At the present time, it is not possible to relate these effects clearly to defined steps in the production of the plant viruses.

Of some interest is the report of the secretion of an extracellular α-amylase by virus-induced tumor tissue of the root of Rumex acetosa (Nickell and Brakke, 1954). The release of the enzyme was not due to cellular breakdown and could not be detected in cultures of normal root tissues. The problems of the origin of the enzyme seem to be similar in some respects to those posed by the Klebsiella system.

In the study of animal cells infected by many types of virus, e.g., yellow fever, lymphocytic choriomeningitis, etc., Bauer (1949) has reported the phenomenon of an apparent increase of xanthine oxidase. This has also been observed for influenza virus-infected tissue whose ability to oxidize many other substrates is virtually unchanged (Sellers and Jann, 1954). The causal relations of this change are not known, but it might be imagined that in virus-infected cells the metabolism of the nucleic acids is deranged in such a way as to release purines which induce the production of enzyme.

As noted above, the study of biochemical changes in cells infected in tissue culture has been begun. However, few satisfactory direct analyses of such cultures have been reported. Although Kovacs (1956a, b) has made many analyses of normal and poliomyelitis-infected cultures and has stated that infected cells show a marked drop in acid and alkaline phosphatase levels, it is not possible to correlate the stage of infection with the reported enzyme content of the cells.

One of the most elegant attempts to correlate biochemical events with virus infection was made in the study of the pathogenesis of poliomyelitis. The effect of infection obviously produces cell damage, e.g., chromatolysis of Nissl substance without significant mitochondrial damage. However, the inability to analyze infected cells as such obscured the possible significance of direct analyses and led to an effort to simulate these effects (chromatolysis) by sectioning peripheral nerves. Then it was discovered that during this type of induced chromatolysis the damaged cell is refractory to virus infection (Howe and Bodian, 1941). Thus it became possible to study the enzymatic changes coincident with the virus-resistant state in degenerating and regenerating cells (Gersh and Bodian, 1943; Bodian and Mellors, 1945, Howe and Mellors, 1945; Howe and Flexner, 1947, Bodian and Mellors, 1947). Although such studies were partially extended in the cytochemical work of Hyden (1947), their early promise has not been pursued.

SOME APPROACHES TO PROBLEMS OF DUPLICATION AND INHERITANCE

Several powerful and ingenious technics have been employed to explore the questions of the fate of infecting viral substance and of the mechanism of transfer of genetic information. The approaches to the latter aspect of the problem have attempted to identify the minimal structure responsible for coding inheritable characters by the addition to cells of purified viral fractions, e.g., nucleic acids, and examining for the production of virus. Such a study is directed primarily to the analysis of the division of labor in a virus particle.

In the experiments described below, the problem to be explored is that of the material coupling between the transfer of the code and the multiplication of viral substance. Is the code used and discarded or destroyed during utilization? Is the information transferred to a new code in a non-nucleic acid intermediate? Is the infecting nucleic acid self-duplicating? Although these and many other questions

sensitive photographic emulsions The particles formed tracks emanating from the site of deposition of the P^{32} containing fragment. From a knowledge of the half lifetime of P^{32} the specific activity of the P of the phage, and the number of individual tracks emanating from a star observed microscopically in a nuclear emulsion, as presented in Figure 29, it is theoretically possible to calculate the number of P atoms in the source of the star Ghosted phage particles were reported to contain two types of DNA, one of which was about 40 per cent the molecular weight of the total DNA of the phage (ca 45 million) whereas the remainder, undetected by this technic, consisted of smaller fragments (ca 8 million molecular weight) Parenthetically, it may be added that phage DNA has been reported to be separable on columns into two chemically distinct fractions (Brown in Levinthal and Thomas, 1957), but not so separable in ultracentrifugation (Cohen, 1957b)

Using the star technic, one large fragment equivalent to about 40 per cent of the phage DNA is reported to be transferred to the bacterium and a fragment of half this size is found in the first generation progeny In the second and subsequent generations derived from these first-generation progeny the 20 per cent fragment is transferred intact Thus, this result appears to be consistent with the conservation of a single thread template as suggested in the Watson-Crick hypothesis concerning the self-duplicability of DNA That the material continuity of such a fragment is in fact associated with the transfer of inheritable characters has yet to be proved

Another test of the transfer of parental P^{32} arose from the observation that phage containing highly radioactive P^{32} die at a rate proportional to the number of radioactive atoms which they contain, as a function of the decay of P^{32} to S^{32} (Hershey et al, 1951) Exploration of this phenomenon as a measure of the P^{32} contained in progeny by Stent and colleagues (Delbruck and Stent, 1957) has also revealed transferred DNA to be contained in a few phage particles This DNA tended also to be conserved However, the data of Stent et al are not entirely in agreement with the hypotheses of Levinthal (see Hershey and Burgi, 1956, Delbruck and Stent, 1957)

Nevertheless, in addition to the potential biologic importance of the Levinthal experiment, the star technic represents a fundamental contribution to the methodology of study of the fate of very large single biologically active molecules Its application in this system points up the technical advantages of using viral systems containing minimal numbers of genetically active molecules in the study of the chemical basis of inheritance not only in contrast with the uninterpretable systems of higher organisms but also vis-à-vis the transforming systems in pneumococci, etc, in which the unfractionated genetic complement contains hundreds of DNA molecules

Once nucleic acid has entered cells, several technics may be used to determine its subsequent fate A powerful tool has been that of irradiating infected cells with ultraviolet light or x-ray and comparing the rates at which free virus and virus-infected centers lose the ability to produce virus The technic was first applied to phage systems (Luria and Latarjet, 1947, Latarjet, 1948, Benzer, 1952) and was used to show that during the first 7 minutes the infectious unit of T_2 possessed the same sensitivity within the cell as it did before infection Thus, in this interval, the injected DNA neither multiplies nor transfers its information to less-sensitive units T_7-bacterium completes maintained the sensitivity of free T_7 through 4 minutes of a short latent period After 7 minutes, the sensitivity of T_2-bacterium complexes fell rapidly, whereas T_7 complexes essentially retained their sensitivities after the multiple unit phase of the curve was passed Thus, the later phases of the multiplication of these viruses appeared to be significantly different

With the plant viruses, it is possible to compare the sensitivity of the free viruses with that of their infectious nucleic acids It has been found that the sensitivities of the nucleic acids of different strains of tobacco mosaic virus were identical, although the intact viruses possessed different sensitivities to ultraviolet radiation (Siegel et al, 1956) Irradiation of tobacco leaves infected by these nucleic acids showed that the infectious centers also were as sensitive as the nucleic acids (Siegel et al, 1957). However, immediately after infection with intact virus, the infectious

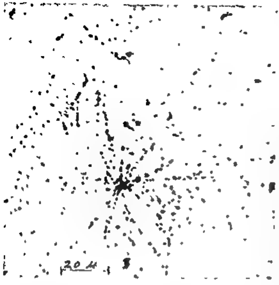


FIG. 29. A photomicrograph of a star produced in sensitive emulsion by the emission of β-particles from a site of decaying P32 (Levinthal, C, and Thomas, C A., 1957, The molecular basis of genetic recombination in phage *in* McElroy, W, and Glass, B [eds], Chemical Basis of Heredity, pp 735-743, Baltimore, Johns Hopkins Press)

only one phage particle, it might be inferred that the bacterial chromosome had only one site available for prophage formation

Comparable experiments on bacterial transformations have been performed recently with P^{32}-DNA (Lerman and Tolmach, 1957; Fox, 1957) and the percentage of transformations is found to be directly proportional to DNA uptake The transformation of a single character appears to require the adsorption of about 500 molecules of DNA, *i e*, in these cases the equivalent of an entire bacterial genome which would have a single unit of effective transforming DNA

As noted earlier, influenza virus can be labeled with P^{32} present in phospholipid and nucleic acid If chorio-allantoic membrane is analyzed 90 minutes after infection with P^{32}-labeled virus, some P^{32} is found in the low-salt extractable nucleoprotein of the infected membrane and some lipid-P^{32} is degraded to form nonsedimentable material (Hoyle and Frisch-Niggemeyer, 1955) Of considerable interest is the presence of a large proportion (25%) of membrane-bound P^{32} in the cell nucleus in a form extractable by a nucleoprotein solvent, *i e*, M NaCl The authors interpreted this data to signify that on entry into the host cell the influenza virus particle is broken down Phospholipid was destroyed, and the nucleoprotein released, at least part of its nucleic acid, to become associated with the cell nucleus.

Hoyle and Finter (1957) have studied the fate of infecting influenza virus labeled with radioactive methionine In this case S^{35} does not become associated with the cell nucleus. Most of the S^{35} (70%) remains associated with particles of size comparable with virus, which are thought to be envelope protein, since none is present in infectious virus Some 10 to 20 per cent of the S^{35} is recovered as low molecular fragments, suggested to be derived from the degradation of the viral nucleoprotein released from viral envelope.

In the hypothesis of Watson and Crick (1953) the two threads of the helical coil of DNA are paired by complementary bases in such a way that each single thread may organize the duplication of a complementary thread The successive fragmentation of the DNA in parent to progeny experiments implied the nonconservation of either thread of the template. However, it has been suggested that the figure of up to a 50 per cent yield of P^{32} in experiments involving isotope transfer from parent to progeny arise from the technical and biologic difficulties of (1) preparing completely viable phage preparations, (2) superinfection breakdown, (3) early lysis of infected cells with loss of intermediate precursors, (4) readsorption of released virus on bacterial debris Hershey and Burgi (1956) have supported this view experimentally As indicated earlier, they have also obtained evidence that the transfer of C^{14}-labeled bases from parental virus occurred in the same ratio as they existed in phage DNA and that a dilution of any parental base could not be effected by competition with exogenously supplied thymidine. Thus, viral DNA does seem to be transferred in large polynucleotide fragments, contrary to the earlier results reported above

An ingenious technic was devised to test this possibility (Levinthal, 1956, Levinthal and Thomas, 1957a) The β-particles emitted by decaying P^{32} in DNA labeled with this isotope were detected by exposure to very

numbers of reactions culminating in DNA replication. Such a rate could be determined for example by the number of enzyme molecules making available a critical deoxyribotide triphosphate

Studies of the sizes of the DNA and protein-precursor pools have revealed that the former is considerably greater, suggesting that the DNA need not be formed within an intact phage skin (Hershey et al., 1954) If a large pool of T_2 viral DNA is permitted to be synthesized in chloramphenicol-inhibited bacteria, this DNA can be encased subsequently by phage protein which the infected cells make when chloramphenicol is removed from the system (Hershey and Melechen, 1957) However, the structural features of the molecules within this intracellular DNA pool are far from clear, since it has not been demonstrated that this material is indeed free despite the existence of some electrophoretic (Singer et al., 1952) and ultracentrifugation data (Watanabe et al., 1955) on extracts of infected cells

Even if phage DNA is self-duplicating, this experiment does not mean that the pool of free DNA directs subsequent protein synthesis, since this may, in fact, be determined by the synthesis of other components in the early phase of infection before the synthesis of phage protein and DNA normally begin (Barry, 1954, Maaløe and Symonds, 1953) Indeed, if infected cells are irradiated to block DNA synthesis after it has already begun, the synthesis of phage antigen continues, implying that the protein-synthesizing mechanism has, in fact, been set by substances more resistant to radiation than is DNA (Watanabe, 1957) At the outset of infection, the functions of DNA duplication and synthesis of phage protein are equally sensitive to radiation of the infected cell Thus, the code for specific protein synthesis seems to be transferred to something other than DNA.

If the synthesis of viral protein and nucleic acid do occur separately, as has been suggested for the bacterial and plant virus systems, the problems of assembly are critical reactions Although the assembly of nucleic acid and protein to form tobacco mosaic virus appears to occur spontaneously in an adequately interdigitated way, as described in Chapter 2, it is very difficult to conceive of this occurring in a similarly simple reaction in the production of intact phage, although such a phenomenon is inferrable from the many experiments reported in this chapter, e.g., phenotypic mixing, coating of phage DNA, etc.

At the present time, the kinetics of development of influenza virus is also consistent with the possibility of a separate development of hemagglutinin and soluble nucleoprotein which are coated together shortly before viral release On the other hand, the development of vaccinia virus viewed in the electron microscope suggests for the time being a more closely integrated synthesis of DNA within a protein shell At present, there is as yet too little known about late stages of assembly in any viral systems to permit a serious comparison of their mechanisms

A UNIQUE CASE OF EXTREME PARASITISM-HYDROXYMETHYLCYTOSINE AND T-EVEN PHAGE SYSTEMS

It is the purpose of the author in this section to record biochemical phenomena for which there are no known biochemical precedents in normal systems Although the generalization of past experience and approaches can facilitate progress, the research worker must also be prepared for new and different phenomena, which he must be prepared to pursue without existing precedent

In the experiments with T-even phage systems presented above, it was determined that the patterns of nucleic acid metabolism and protein and enzyme synthesis were markedly changed by infection This occurred without apparent changes in energy supply and respiration, nevertheless, the infected cells developed a profound alteration in the balance of metabolic pathways used to metabolize glucose However, this alteration in the mechanism of glucose utilization was controlled at a level of metabolism other than that of the early metabolism of glucose. All of these phenomena can be interpreted in terms of the net production of viral DNA with a concomitant cessation of synthesis of bacterial DNA and RNA How can the shift to the increased accumulation of this substance be explained?

A simple explanation stems from the dis-

centers were approximately as sensitive as the intact virus, i e, less sensitive than were the infectious centers produced by the respective nucleic acids These sensitivities remained constant for hours, the duration of this period depending on the virus used It appeared that free nucleic acid multiplied immediately, whereas the viruses within virally induced infectious centers, but not nucleate induced centers, multiplied only after shedding their protein coats, a process taking some hours. Comparable studies have not yet been performed in animal virus systems

In studying the intracellular fate of these viral nucleic acids and the problem of nucleic acid metabolism in general, attempts have been made to apply ribonuclease and deoxyribonuclease The study of the effects of these enzymes has not yet produced clear results with phage systems (Kleczkowski and Kleczkowski, 1954, Fraser and Mahler, 1957; Jerne and Maaløe, 1957). However, ribonuclease has yielded interesting results with RNA virus systems. For example, when ribonuclease is infiltrated into tobacco leaves, this treatment inhibits multiplication of tobacco mosaic virus even if infection had occurred up to 2 hours before addition of the enzyme (Hamers-Casterman and Jeener, 1957) This enzyme similarly inhibits the multiplication of influenza virus in chorio-allantoic membrane in tissue culture (LeClerc, 1956) Again, this effect is manifest only within 2 hours after infection The inhibitory effect of the enzyme on virus multiplication was observed without change in the incorporation of C^{14}-phenylalanine, although the incorporation of C^{14}-adenine was inhibited markedly

It would appear that nucleic acid initiates specific duplication in these systems but how is this effected? In the phage systems does DNA duplicate itself with the production of RNA and viral protein as a concomitant by-product? Or does it compel the synthesis of RNA which directs viral protein synthesis, with one of these then directing DNA synthesis? Or does the DNA compel, with the concomitant by-product RNA, the synthesis of protein, which then directs DNA synthesis? It is very difficult to say at present. As noted earlier, it is known in the T-even phage systems that a prior synthesis of protein containing deoxycytidylate hydroxymethylase is required before DNA synthesis can occur. However, other phage systems also show this requirement for protein synthesis despite the absence of hydroxymethyl cytosine in these phage DNA's so that it may be supposed that early protein syntheses of unknown function are required in all systems

That this protein may have some genetic function has been suggested as a result of the work of Stent (1955) and Stent and Fuerst (1956) Using highly radioactive virulent or temperate P^{32}-phage to infect bacteria, phage development was allowed to proceed for various times before the infected bacteria were frozen and stored. Immediately after infection the ability of the infected cells to produce phage could be shown to decrease as a function of radioactive decay of P^{32}. However, after a few minutes of intracellular phage development the ability of these cells to produce phage became independent of radioactive decay. One hypothesis to explain this result would be that the code for phage production was transferred to moieties free of P, perhaps to protein (Stent, 1955) In support of this concept are the experiments of Tomizawa and Sunakawa (1956) who have demonstrated that, despite the synthesis of viral nucleic acid, the inhibition of protein synthesis in chloramphenicol-inhibited infected bacteria prevents a change in the radiation sensitivity of infected cells

On the other hand, as described in Chapter 7 in greater detail, other workers have supposed that viral DNA is self-duplicating in the model of Watson and Crick Phage antigens do not exist in uninduced lysogenic bacteria (Miller and Goebel, 1954) and in conjunction with the experiment of Goodgal (1956) this may be suggested to signify that prophage is naked viral DNA which multiplies in this form As described by Luria (1951) and Tanami (1957), the frequency distribution of spontaneous phage mutant clones suggests that the replication of viral genetic units proceeds in such a way that replicas themselves may serve as patterns for additional replications This is evidently consistent with the concept of viral DNA as a self-duplicating unit Furthermore, this picture is not inconsistent with the observed linear production of phage DNA, since the latter may only reflect some rate limiting step in the large

esterase activity (Cohen, 1953). Subsequently, it was found that such enzyme-resistant fragments contained derivatives of HMC in which glucose was attached through glycosyl linkage to the hydroxymethyl group (Volkin, 1954; Sinsheimer, 1954, Cohen, 1956, Jesaitis, 1957) Thus, this new substituent renders these viral DNA's more resistant to types of enzymatic activity that completely degrade host DNA

It has been shown that the glucose contents of the T-even phages are in the order $T_2r^+ < T_4r^+ < T_6r^+$, although their HMC and other base contents are identical. The glucose to HMC ratios in these viruses are 0 8, 1 0 and 1 6, respectively Preparations of the "r" phages have been found to contain more glucose than do homologous r^+ phages (Cohen, 1956), however, it has not been proved that such results do not arise from contamination of these more difficultly purifiable phages A correlation has been observed between the infectivity of a T-even phage and the glucose content of its DNA (Streisinger and Weigle, 1956, Sinsheimer, 1956) A new type of inheritance has been observed by these workers in which the glucose content of T_2 produced in a bacterium simultaneously infected with T_4 is raised to that of T_4 Such particles continue to multiply as T_2, although maintaining the glucose content of T_4 Thus, gross glucose content does not entirely determine T_2ness, although it certainly establishes some properties of wild type T_2 particles

On treatment of T-even phage DNA with deoxyribonuclease and phosphodiesterase, about 25 per cent of the HMC is liberated as mononucleotides T_2-DNA liberates a mixture of nonglucosylated and monoglucosylated nucleotides, T_4-DNA liberates only monoglucosylated nucleotides, and T_6-DNA releases a mixture of nonglucosylated and diglucosylated nucleotides (Jesaitis, 1957) A smaller amount of monoglycosylated nucleotides and a relatively larger amount of diglucosylated HMC-containing dinucleotide have also been found in the latter instance (Cohen and Lichtenstein, 1958) Thus, glucose modifies the HMC sufficiently to suggest that the insertion of particular types of HMC nucleotides into the DNA chain probably does confer genetic specificity upon this chain However, it is not possible to say at present how glucosylation occurs or how the selection of particular HMC nucleotides is effected In addition, it might be asked if the presence of diglucosyl HMC nucleotides in T_6 does not induce the mechanism for adding a second glucose to a monoglycosylated HMC nucleotide and if indeed a similar mechanism does not account for conferring the glucose contents of T_4 on T_2 particles during mixed infections

Thus, HMC appears to play at least 3 major roles in the multiplication of T-even phages:

1 It helps to explain the parasitism and trapping mechanism which diverts bacterial metabolism to making virus

2 It provides a point of attachment for glucosyl moieties which confer stability to DNA by protecting phosphodiester linkages containing HMC nucleotides

3 Various glycosylated states of HMC nucleotides modify the order of the polynucleotide chain, in part determining speciation among the T-even viruses

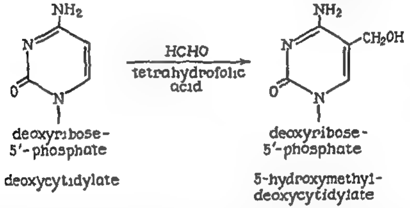
CONCLUSION

Despite the fact that historical accident focused a large portion of biochemical study on the unique T-even phages, their extreme virulence and other special properties facilitated the development of a biochemical methodology in which a large number of biochemical technics were applied successfully to the analysis of virus-cell interactions and the steps in virus multiplication As we have seen, studies on these unique systems have contributed to biochemistry in general, providing insight into problems of the metabolism of carbohydrates, of 1-carbon fragments, and of polymer structure and biosynthesis, with particular reference to the chemistry of duplication and inheritance. The methodology which has been developed has already been applied in part to some animal and plant virus-cell systems and will be applicable to many others after their elementary biologic properties will have been established Until the biochemical behavior of the infected animal cell, the unit of viral disease, is clarified, it does not appear fruitful to consider in detail the problem of the biochemical patho-

covery of a new and unique pyrimidine, 5-hydroxymethylcytosine (HMC) in the DNA of the T-even phages (Wyatt and Cohen, 1953). The normal pyrimidine, cytosine, although present in bacterial DNA and RNA, is not present in the viral DNA In fact, the cytosine deoxyribotide of bacterial DNA is converted to the HMC nucleotide of viral DNA The reaction involves the hydroxymethylation of cytosine deoxyribotide in the presence of tetrahydrofolic acid to form hydroxymethylcytosine deoxyribotide (Flaks and Cohen, 1957)

T-even phage and increases to a maximum 15 minutes after infection. It may be noted that the rate of viral DNA synthesis is maximal between 7 to 10 minutes, and more enzyme continues to be produced than is necessary to attain this maximal rate. Infection in the presence of 5-methyl tryptophan prevents its appearance; subsequent addition of tryptophan then results in the production of enzyme. Thus, the production of enzyme seems to require protein synthesis

The production of the enzyme need not be tied to the duplication of DNA and virus



The reaction is irreversible, and the enzyme is present in excess, permitting a trapping of all the deoxycytidylate formed and rendering it unavailable for synthesis of normal bacterial DNA. It may be supposed, although not yet proved, that the trapping action may extend to cytosine ribotide essential for the production of bacterial RNA, if the conversion of deoxycytidylate from cytidylate is hastened thereby The deficiency of cytosine derivatives in preventing the synthesis of bacterial nucleic acids may be expected to prevent the gross production of bacterial polymers, particularly proteins, associated with the nucleic acids

Why does this trapping action not occur during normal growth? The deoxycytidylate hydroxymethylase is not present in normal bacteria nor can it be released by various types of disintegration of normal bacteria It cannot be found in bacteria infected in the absence of HMC-containing DNA, e.g., T_1 On the other hand, it is not detectable within T-even phages The enzyme begins to appear within 0 to 3 minutes after infection by a

duplication Thus, phage extensively inactivated by ultraviolet light will induce essentially normal formation of enzyme under conditions in which virus does not multiply (Flaks and Cohen, 1958) It may be supposed that bits of virus DNA, possibly from a fraction which does not serve as a template for virus multiplication, act as inducer It had been found earlier that protein synthesis continued under conditions of infection with ultraviolet-infected phage (Cohen, 1951) although DNA synthesis need not continue. In this unique system, it appears possible that a portion of the DNA may induce an enzyme essential to the production of a component essential to the duplication of genetic material.

The existence of the hydroxymethyl group provides a point of attachment for additional substituents. Fractions of the DNA of the T-even phages have been extraordinarily resistant to phosphoesterases These fractions proved to contain HMC, and a preliminary acid hydrolysis was necessary to make HMC-containing nucleotides available to phospho-

esterase activity (Cohen, 1953) Subsequently, it was found that such enzyme-resistant fragments contained derivatives of HMC in which glucose was attached through glycosyl linkage to the hydroxymethyl group (Volkin, 1954; Sinsheimer, 1954, Cohen, 1956; Jesaitis, 1957). Thus, this new substituent renders these viral DNA's more resistant to types of enzymatic activity that completely degrade host DNA

It has been shown that the glucose contents of the T-even phages are in the order $T_2r^+ < T_4r^+ < T_6r^+$, although their HMC and other base contents are identical The glucose to HMC ratios in these viruses are 0 8, 1 0 and 1 6, respectively Preparations of the "r" phages have been found to contain more glucose than do homologous r^+ phages (Cohen, 1956); however, it has not been proved that such results do not arise from contamination of these more difficultly purifiable phages A correlation has been observed between the infectivity of a T-even phage and the glucose content of its DNA (Streisinger and Weigle, 1956; Sinsheimer, 1956). A new type of inheritance has been observed by these workers in which the glucose content of T_2 produced in a bacterium simultaneously infected with T_4 is raised to that of T_4 Such particles continue to multiply as T_2, although maintaining the glucose content of T_4 Thus, gross glucose content does not entirely determine T_2ness, although it certainly establishes some properties of wild type T_2 particles

On treatment of T-even phage DNA with deoxyribonuclease and phosphodiesterase, about 25 per cent of the HMC is liberated as mononucleotides T_2-DNA liberates a mixture of nonglucosylated and monoglucosylated nucleotides, T_4-DNA liberates only monoglucosylated nucleotides, and T_6-DNA releases a mixture of nonglucosylated and diglucosylated nucleotides (Jesaitis, 1957) A smaller amount of monoglycosylated nucleotides and a relatively larger amount of diglucosylated HMC-containing dinucleotide have also been found in the latter instance (Cohen and Lichtenstein, 1958) Thus, glucose modifies the HMC sufficiently to suggest that the insertion of particular types of HMC nucleotides into the DNA chain probably does confer genetic specificity upon this chain However, it is not possible to say at present how glucosylation occurs or how the selection of particular HMC nucleotides is effected In addition, it might be asked if the presence of diglucosyl HMC nucleotides in T_6 does not induce the mechanism for adding a second glucose to a monoglycosylated HMC nucleotide and if indeed a similar mechanism does not account for conferring the glucose contents of T_4 on T_2 particles during mixed infections

Thus, HMC appears to play at least 3 major roles in the multiplication of T-even phages·

1 It helps to explain the parasitism and trapping mechanism which diverts bacterial metabolism to making virus

2 It provides a point of attachment for glucosyl moieties which confer stability to DNA by protecting phosphodiester linkages containing HMC nucleotides.

3 Various glycosylated states of HMC nucleotides modify the order of the polynucleotide chain, in part determining speciation among the T-even viruses

CONCLUSION

Despite the fact that historical accident focused a large portion of biochemical study on the unique T-even phages, their extreme virulence and other special properties facilitated the development of a biochemical methodology in which a large number of biochemical technics were applied successfully to the analysis of virus-cell interactions and the steps in virus multiplication As we have seen, studies on these unique systems have contributed to biochemistry in general, providing insight into problems of the metabolism of carbohydrates, of 1-carbon fragments, and of polymer structure and biosynthesis, with particular reference to the chemistry of duplication and inheritance The methodology which has been developed has already been applied in part to some animal and plant virus-cell systems and will be applicable to many others after their elementary biologic properties will have been established. Until the biochemical behavior of the infected animal cell, the unit of viral disease, is clarified, it does not appear fruitful to consider in detail the problem of the biochemical patho-

genesis of viral disease in an intact multicellular organism Indeed, questions relating to this problem have not yet even been posed in suitable forms; in general, it is difficult to run before learning to walk.

portance, and the main motivation of work in this field was based on the need for control of these infections In a similar way, the work on animal viruses was closely linked to medical and veterinary practice

Animal virology grew up largely as an offshoot of pathogenic bacteriology and, in the beginning, was largely in the hands of pathologists Both medical and veterinary virologists were mainly interested in the broad, general aspects of disease, the mode of virus transmission, the insect vector, methods of virus isolation and antibody measurement as aids to laboratory diagnosis, and the study of the development and the duration of systemic immunity. Apart from studies on inclusion bodies, relatively little emphasis was placed on the basic biologic unit, the virus-infected cell. The reasons for this neglect were in part technical, the difficulties of carrying out virus studies in tissue culture and of cultivating pure lines of mammalian cells But a more important factor was the immediate enormous practical success which followed the general approach A good example is urban yellow fever, which was completely controlled through the limited knowledge that the filterable agent circulated in the blood of an infected man and was transmissible to other men by mosquitoes On the other hand the study of the virus-infected cell, admittedly a recent approach, has had very little direct impact on man's ability to control virus infections of either plants or animals

It is at the level of cellular infection that the unity of the several branches of virus research is demonstrated most readily, and the most important single event in the development of virology as an independent science was the discovery of bacterial viruses (Twort, 1915, d'Herelle, 1917) Early development of this field was slow Efforts were dissipated over a wide variety of available agents A number of attempts were made to use bacteriophage therapeutically in human bacterial infections, but the results were disappointing and, when interest in bacteriophage was renewed in the late 1930 s, investigators were not looking for immediate medical or economic consequences, the primary interest was biologic Virus studies were focused consistently, for the first time, at the level of the infected cell, and the results were exceedingly fruitful Bacterial virology has become of enormous importance in various fields of biology, in cytology, biochemistry, bacterial genetics, general genetics and animal virology

The effect of this development on animal virology has been especially marked. Studies on phage multiplication, on the eclipse phase, on genetic constitution, on multiplicity reactivation and cross-reactivation and on phenotypic mixing have served as models for studies with animal viruses Even phage technics, such as plaque formation, for particle enumeration have been applied directly to animal viruses and have been carried into this field by students of bacteriophage Concomitant with this development has been an increased interest in the study of isolated mammalian cells, and it is tempting to speculate that the study of cells in tissue culture will eventually complement virologic studies just as bacterial and bacteriophage studies have become interdependent

The study of plant viruses presents both outstanding advantages and disadvantages for solving virus problems Plant viruses are relatively simple in structure, they can be obtained readily in great quantity and are easily purified by chemical methods. On the other hand, plant virus particles infect with exceedingly low efficiency, they are difficult to titrate with accuracy, and so far infection has not been studied successfully at the cellular level Plant viruses have proved to be useful models Interference between viruses and infection of cells with naked RNA was accomplished first with plant viruses and later with other agents.

In the ensuing account bacterial animal plant and insect infections with viruses are described separately. For each group a model virus is used the "T" viruses in the case of bacteriophage, the myxo group (influenza mumps, Newcastle disease and fowl plague) for animal viruses, and tobacco mosaic as a representative of plant viruses In each case, the description of these particular agents will form the backbone of the discussion of multiplication Material with other viruses will be used to illustrate special points The distribution of the available experimental evidence almost forces this stratagem, and the justification of generalizing from these models will

Virus-Host Cell Relation

INTRODUCTION *

Virology is a new science with origins in widely scattered and independent developments involving plant, animal, bacterial and insect infections The early emphasis in the study of these varied agents was on the *systemic* effects that they produced. This tended to promote the separate development of the various branches since, in terms of symptoms, it is difficult to discern much connection between yellow fever and mosaic disease of tobacco, for example, although both are caused by small subcellular particles The existence of general principles in virology has become apparent only in recent years since virus infections have been studied with increasing success at the cellular level, and the development of a virologic science is still in a fairly primitive stage While there are numerous gaps in our knowledge which dictate the use of restraint in formulating new generalities, the recent impact of one branch of the field on another has been so great and of such importance that no one can any longer doubt the heuristic as well as the didactic value of the comparative approach to this science.†

Extracellular virus particles, having no intrinsic metabolism, are in a relatively stable state of suspended animation which permits an accurate description of their chemical and physical properties However, during most of their *intracellular* life, viruses are undergoing constant change, and they become transformed so markedly that they are no longer recognizable by conventional methods Virus adsorption is followed by virus penetration, and the stable infective form is transformed into a vegetative noninfective stage, after which there is replication and biosynthesis of individual virus components, assembly of these components in a process called "maturation" and, finally, the extrusion of new virus from the cell The study of these events constitutes the core of virology The aim of the author in this chapter will be to discuss viruses on a comparative basis and to confine the discussion, wherever possible, to infection at a cellular level The weakness of this approach is its prematurity, since the study of animal viruses in isolated cells is just beginning

The inception of virology (Iwanowski, 1892) coincided with the failure of a standard bacteriologic tool, the earthenware filter, to give a pathogen-free filtrate of the sap of tobacco plants which had been infected with mosaic disease virus In exploiting this finding, plant pathologists confined their attention primarily to plants of agricultural im-

"abo- ... afer ... isive formulation of virology as a science in his textbook *General Virology* (Luria, 1953) He has also published a subsequent review on *The Reproduction of Viruses,* (Luria, 1958) which was made available by the author in prepublication form, and this article, together with the textbook, have been freely used in this chapter as a model for both form and substance

in nature is temperate in character and is carried in lysogenic form. Many bacteria are lysogenized by more than one type of virus and the number of virus types is large, especially if minor differences are counted.

Among vertebrates, a few virus infections of fish are known (fishpox, salmon poisoning), and a tumor virus of the leopard frog is common. On the basis of experience with mammals, it is possible that virus infections of cold-blooded vertebrates may be common but undetected because of the lack of close observation. Among birds, virus infections are extremely common. In the domestic fowl they are responsible for a wide variety of pathologic conditions, including malignant tumors. Among mammals, it is a reasonable guess that none are free from infection with viruses, although the domestic and laboratory species furnish the largest number of established examples.

Among insects, viruses are known which infect hymenoptera, diptera and lepidoptera.

CLASSIFICATION OF VIRUSES

Numerous attempts have been made to classify all known viruses under one comprehensive system. No one has yet evolved a satisfactory solution to this problem, which may be partly due to the fact that so little is known concerning the origin and the evolution of viruses that the various schemes contain no continuous thread of natural significance. Attempts have been made to classify viruses on the basis of host range, size, morphology, type of lesion produced, the antigenic constitution and other criteria. Usually it is found that a single criterion (antigenic relationship, for example) works well with one group of agents but produces paradoxes in another group. Because of the very tentative character of most of these schemes, they will not be discussed in detail.

Animal virologists (Andrewes, 1954) have worked out a preliminary plan in which 5 small groups of animal viruses are described. Agents in these groups are similar morphologically and have at least one other feature in common. Only a small fraction of the known animal viruses fall within this classification.

1. *The Chlamydozoaceae* (mantle viruses). This includes psittacosis, ornithosis, trachoma, inclusion conjunctivitis and lymphogranuloma venereum viruses. These agents are of uniformly large size. They are morphologically complex and are all sensitive to antibiotics. In the opinion of some virologists, these agents are more closely related to the rickettsiae than to viruses and do not properly fall within the scope of this classification.

2. Pox viruses (Fenner and Burnet, 1957). This group includes the viruses of smallpox, vaccinia, cowpox, ectromelia (mousepox), fowlpox, molluscum contagiosum, myxoma and fibroma. They are all fairly large viruses, they have antigens in common, and all produce similar cytoplasmic inclusions. Cells infected with these agents show varying degrees of proliferative as well as necrotic reactions.

3. This group consists of herpes virus, B virus, pseudorabies and varicella. Like the pox viruses, they are capable of causing vesicles in the skin, and they have a tendency to infect the central nervous system.

4. Poliomyelitis viruses, types I, II and III, and mouse poliomyelitis (von Magnus et al., 1955). These are enteric viruses which spread occasionally to the central nervous system.

5. Myxoviruses (Andrewes et al., 1955). This group includes influenza A, B, C and D, fowl plague virus (FPV), Newcastle disease virus (NDV) and mumps. All of these agents possess an enzyme capable of splitting off neuraminic acid derivatives (Gottschalk, 1957) from some common mucoproteins.

SEROLOGIC PROPERTIES OF VIRUSES

All viruses are good antigens or, more precisely, they contain good antigens, and the virus-antibody reaction is of special interest for a variety of reasons. From the clinical and epidemiologic standpoint interest stems from the fact that, in higher organisms, the development of antibodies as a response to infection is closely correlated with the development of immunity. From the diagnostic standpoint, circulating antibodies are of great retrospective value in establishing the etiology of infections. However, the applied aspects of serology are covered in chapters concerned with specific virus diseases and with serologic reactions (Chap. 10).

The present chapter deals with the kinetics of virus-antibody reactions and with the use

have to be judged in the light of accumulating evidence on other agents.

DEFINITION OF A VIRUS

For reasons of clarity, it is desirable to try to define what is meant by a virus. Luria (1953) has defined viruses by introducing four basic restrictions (1) viruses are entities, (2) viruses are submicroscopic in size, (3) viruses reproduce only inside specific living cells, and (4) viruses can be introduced into these host cells from without

The notion that a virus is an entity with specific characteristics and specific structure is a fact which is made clear in both this and other chapters of this book Evidence regarding the microscopic structure is given in Chapter 2 These details of structure, plus the discovery of the manner in which genetic traits are carried and transmitted in viruses, have done more than anything else to dispel the once widely held notion that viruses are merely degraded or slightly altered normal cell constituents

Limitations on the size of viruses seems, at first, to be arbitrary, not to say somewhat questionable, since the total range is so very great Actually, the outmoded term "filterable viruses" arose from the fact that earthenware filters effected a fairly satisfactory separation between most viruses and most bacteria Viruses range in size from those which are of the approximate dimension of large protein molecules on up to those which are barely visible in the light microscope

The third requirement states that the agent, *in order to be a virus, must be able to multiply within specific living cells* The word "specific" implies a definite but limited range of suitable host cells The term "living" may be regarded as describing a state of metabolic activity or of ability to mobilize energy rather than capacity to divide, because the latter is often lost immediately after the virus enters the cell.

Some of the smallest bacteria (pleuropneumonialike organisms and micro-organisms found in sewage) meet the size requirements but are eliminated because they are not obligatory intracellular parasites On the other hand, certain bacteria and algae which multiply only within cells are large and are eliminated by the size requirement.

The fourth restriction, that the agent can be introduced from without, is a necessary one in order to exclude subcellular particles such as mitochondria or microsomes from the definition It is not impossible that, with increasing knowledge of the origin of viruses, this restriction will come to have less and less meaning.

The difficulties in definition are pointed up by the discovery that naked RNA without accompanying protein from plant viruses is able to infect plants What was once considered to be *the* virus appears to be only a stable vehicle containing the essential infective entity. A chemist, extracting DNA from pneumococci and using it to transform other pneumococci, is doing something operationally very similar to the infection of plant cells with naked RNA, yet common sense tells us that the transforming principle is not a virus. We have clearly reached some kind of borderline of differentiation Luria (1958) has suggested as a unifying view that viruses be considered as "genetically specific cell constituents, containing coded DNA or RNA which can, as one of their genetic functions, determine their own incorporation into specific vehicles for transmission to other cells"

DISTRIBUTION OF VIRUSES IN NATURE

The hosts of all the known viruses fall into four large taxonomic groups (1) flowering plants, (2) insects, (3) bacteria and (4) vertebrates All of the plants which are known to be affected by viruses belong to the classes of angiosperms, or flowering plants No viruses are known which attack lower plants or gymnosperms, but the possibility must be borne in mind that agents for the latter may have remained undetected because of lack of observation Among the angiosperms, the most thoroughly studied infections are in cultivated plants, such as sugar cane, peaches, tobacco, tomatoes and potatoes.

There are very few classes of bacteria for which bacteriophages have not yet been found (Luria, 1953), and they are groups in which technical difficulties in isolation and detection might be expected. Most of the phage found

When a phage-antibody mixture is diluted, one could expect some reactivation of neutralized virus if dissociation of the antibody-virus combination were at all a prominent reaction However, no reactivation takes place on dilution, and the phage-antibody union is regarded [redacted] nondissociable. This lack of reactivation on dilution is not due to any lethal effect of antibody on phage because the antibody can be digested away with papain (Kalmanson and Bronfenbrenner, 1943) or destroyed by sonic vibration (Anderson and Doermann, 1952) and the virus recovered in active form Antisera taken very shortly after the beginning of immunization of an animal are exceptional, and a combination between this early form of antibody and phage [redacted] moderately dissociable (Jerne and Avegno 1956) The explanation of this difference is not clear

Animal viruses, unlike phage, have no specific structure for attachment to the host cell, and there is no evidence so far that an injection mechanism is involved in infecting the cell It is not certain whether the entire virus particle or only part of it enters the host at the time of infection Investigation of the kinetics of neutralization with animal viruses has been hampered by the lack of suitable methods for measurement of surviving virus The older methods of titration in animals have the defect that the entire reaction mixture (virus + antibody) is brought into the host organism at the time of titration This means that the antibody introduced into the test animal has the possibility of continuing to react with virus during the incubation period of the neutralization test This defect is avoidable with the plaque method of virus titration

One of the first principles evolved from the study of virus serology was the "percentage law" (Andrewes and Elford, 1933) This law states that when virus is added to antibody and allowed to come to a state of equilibrium, the proportion (percentage) of virus surviving will be the same regardless of the amount of virus added This law holds reasonably well only when antibody is present in excess

With the plaque method of virus assay, it has been possible to eliminate some of the previous difficulties with studies on neutralization, and this has been used so far with poliomyelitis, Newcastle disease virus and Western

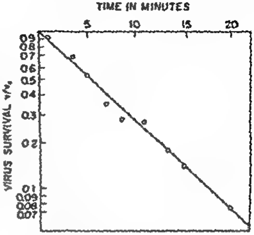

FIG 30 Curve of the kinetics of neutralization of WEE virus showing the residual active virus at different intervals after combining virus and antibody (Dulbecco, et al, 1956, A study of the basic aspects of neutralization of two animal viruses, Western equine encephalitis virus and poliomyelitis virus Virology 2, 162-205)

equine encephalomyelitis viruses With this method, one can study the kinetics of the virus-antibody reaction The rate at which antibody reacts with virus is shown in Fig 30 A small amount of antibody (Dulbecco et al, 1956) was added to the virus, and samples were withdrawn at intervals They were diluted immediately by a large factor so that virus-antibody union would be stopped at once, and the samples were tested for surviving virus The results show that during the inactivation of the first 95 per cent of the virus the proportional rate of inactivation remained constant

In extending this experiment, different concentrations of serum were added to the same amount of another virus, and again the disappearance of active virus with time was measured From this experiment (Figs 31 and 32) it can be seen that the rate of virus disappearance (slope of lines in Fig 31) [redacted] directly proportional to antibody concentration These two experiments show that, within the range investigated the logarithm of the per cent of original virus which remained active was inversely proportional to the time of incubation and to the concentration of antibody

of serology for studying macromolecules The property of infectivity makes it possible to detect single virus particles even at high dilutions, and this, in turn, makes it possible to study the kinetics of the virus-antibody reaction at concentrations which are unique and provide data of interest to virologist and immunologist alike Serology also provides a tool with which subtle differences can be detected between large molecules, differences which remain obscure even after chemical analysis Such a tool is invaluable in identifying the different components of virus particles, in distinguishing these components from host cell substances and in following quantitatively the production of virus subunits in an infected cell before such time as the parts are assembled into mature particles, recognizable by their ability to infect

There are four principal ways of measuring virus-antibody reactions (1) the precipitin or agglutination test; (2) neutralization, (3) complement fixation, and (4) hemagglutination inhibition. Each of these tests has its own areas of usefulness and, while it is conceivable that two of them could measure precisely the same antigen-antibody reactions, this seldom happens in actual practice

The Precipitin Test. Precipitin tests may be performed either with virus particles or on soluble substances found in virus preparations Virus particles may be made to agglutinate or precipitate by homologous antisera, but this requires a high concentration of particles There is a well-established relationship (Merrill, 1936) between the size of a particle and the concentration necessary to obtain visible aggregation or precipitation with antibody. The critical concentration for some animal viruses is as much as 10^{12} particles per ml, and this amount is usually prohibitive for extensive studies Recently, however, the Ouchterlony and Oudin methods for obtaining precipitates in agar gels have been used for virus serology, and this promises to be a useful technic. Plant viruses are frequently typed by the precipitin method, since they are often available in large quantities.

The Neutralization Test. Neutralization may be defined as the loss of the infectious property of a virus particle because of a reaction with antibody. Neutralization is of special interest to the virologist and to the clinician because it is the essence of a major protective mechanism in vertebrates against virus infections. Neutralization is of special interest to immunologists because the reaction offers an opportunity to study antigen-antibody reactions at concentrations which are unique The infective property of viral particles can be measured accurately even at very high dilutions, therefore, the effect of antibody can likewise be measured in concentrations where lattice formation and other events do not complicate the results.

Plant viruses can be neutralized with antiviral rabbit sera, but the kinetics of the reaction have been very little studied, partly because of technical complications, such as the neutralizing effect of normal sera, and partly because of the very low efficiency of normal particles in producing foci on leaves It is doubtful whether the mechanism of neutralization of plant viruses can be the same as that of animal and bacterial agents Animal and bacterial viruses are neutralized by absorption of antibody to attachment sites while, in plant viruses, there is no evidence so far of sites which facilitate the initial stages of infection

Bacterial and animal virus neutralization have so much in common that they can be discussed together profitably Coliphages stimulate formation of at least two antiphage antibodies (as shown by reciprocal absorption) (Lanni and Lanni, 1953), one for the head and one for the tail. An entire phage particle

ever, the absorption of even very large amounts of antibody on the body of the virus has no effect on the ability of phage to infect a cell by injecting its DNA into the bacterium Of the antibody absorbed to the tail, presumably only that absorbed at the tip has an effect in neutralization When phage is mixed with an excess of antibody and the course of inactivation is followed for several hours, it proceeds at an exponential rate, and this first-order reaction suggests that the inactivation of each particle is due to a single event—the absorption of an antibody molecule to a critical site The kinetics of animal viruses are similar and are discussed below.

infective agent by means of the absorption of a single antibody molecule This model will give first-order kinetics consistent with experiment (Figs. 30 and 31) There are two stages of neutralization: (1) the formation of noninfective but adsorbing particles, and (2) the formation of noninfective and nonadsorbing particles To convert a single site to stage 1 requires a single antibody molecule, and to stage 2 (with NDV) requires 2 to 3 molecules (Rubin and Franklin, 1957) To inactivate a virus particle requires that all sites react with antibody or else that the particle attach to the host at a site already occupied by antibody.

Dissociation of Antibody from Virus. Another problem of common importance to immunology and virology concerns the firmness with which specific antibody molecules unite with virus particles It is a matter of both practical and theoretical importance to know whether a virus particle, once neutralized, can be reactivated by spontaneous dissociation of antibody The view from classic immunologic work is that under physiologic conditions, spontaneous dissociation of antigen and antibody is negligible On the other hand, the ability of the virologist to detect activity in single particles at high dilution furnishes conditions for dissociation which have not been examined previously The studies on neutralization of phage by dilution indicate that the phage-antibody complex is completely nondissociable with most sera However, a great number of animal viruses appear to be reactivated by simple dilution of neutral mixtures, and this has led to the expression of the view that animal viruses as a class are *freely* dissociable (Burnet, 1955) Recent evidence makes this conclusion doubtful

A typical example of virus reactivation by dilution is as follows A large amount of influenza virus is to be tested in the allantoic sac Sufficient antiserum is added until the injection of virus and antibody fails to give detectable hemagglutination after incubation Such virus is said to be neutral and operationally, this means that an insufficient number of cells were infected with virus to yield a detectable HA titer However, if the so-called neutral mixture is diluted 10 or 100 times and the same volume (0 1 ml) used to inoculate the allantoic sac, detectable hemagglutinins are produced (McKee and Hale, 1946)

Two interpretations of this experiment are possible (1) The virus yield from the diluted inoculum was due to antigen-antibody dissociation Antigen-antibody dissociation is marked and, when the reagents are diluted, the reassociation reaction rate is reduced markedly, and an increase of active virus results (2) An alternative explanation is that such dissociation is minor or negligible. The so-called neutral mixture actually contains particles which infect, but the presence of large amounts of uncombined antibody in the allantoic sac (from the inoculum) prevents any significant amount of cell-to-cell spread of these infections However, when the "neutral" mixture is diluted, essentially less of the uncombined antibody is put in the allantoic sac The few cells that are infected can infect other cells more efficiently, and a detectable yield results

The deficiency of this technic (the transfer of antibody to the test organism) does not permit direct proof of the dissociation theory, and most animal virus neutralization experiments suffer from this same defect When dissociation-dilution experiments with animal viruses are done by the plaque assay method, this pitfall may be avoided With this technic, the degree of dissociation found is at best very small (Dulbecco et al, 1956), and the results are not radically different from what is obtained with phage If the results with poliomyelitis, WEE and NDV are typical, then dissociation with animal viruses is minor Mandel (personal communication) has shown with poliomyelitis that a very small portion of neutralized virus is dissociable by dilution under physiologic conditions, even in the absence of cells

Another method of dissociating antibody is by displacement of active with inactive virus in a virus-antibody complex Active virus is neutralized, and a great excess of inactivated virus (heat or UV inactivation) is added As a result, active virus appears in the previously neutral mixture This is also clear evidence of at least a low grade of virus-antibody dissociation (Dulbecco et al, 1956) These experiments also show that the virus is not fundamentally altered by the antibody.

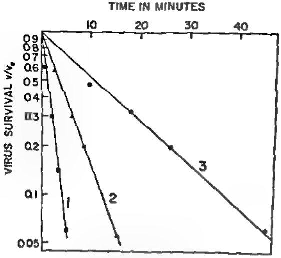

Fig 31 Change in the slope of the kinetic curve for neutralization of poliomyelitis virus (type I), using serum concentrations in a ratio of 10/3 3/1 for curves 1, 2 and 3. (Dulbecco, et al, 1956, A study of the basic aspects of neutralization of two animal viruses, Western equine encephalitis virus and poliomyelitis virus, Virology 2, 162-205)

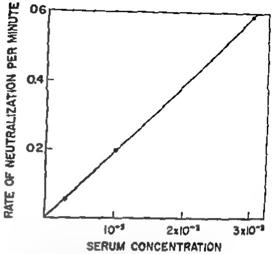

Fig 32. Data taken from Figure 31 in which the rate of virus neutralization per minute is plotted against serum concentration

This relationship may be expressed in the following equations (Luria, 1953).

$$\frac{P}{P_o} = e^{-ktC} \qquad \log_e \frac{P_o}{P} = ktC \qquad \log_{10} \frac{P_o}{P} = 0.43ktC$$

Where "P_o" is the initial virus concentration, "P" is the fraction remaining active, "t" = the time of contact between virus and antibody, and "C" = the concentration of antibody, "k" is a constant which is proportional to the fractional rate of inactivation and is characteristic for a given virus and a given serum. This also expresses the consequences of the percentage law for the case where "C" is large and "t" is long

When the same serum is used with different viruses, the "k" values are an expression of the degree of relatedness of the two agents. Antiserum prepared against one virus naturally gives a low slope with a relatively unrelated agent.

One important feature of the curves in Figures 30 and 31 is that they are straight lines through the origin This is typical of a first-order reaction and strongly suggests that the neutralization of a virus particle is due to a single event—the combination of a molecule of antibody with a critical site on the virus If more than one antibody molecule were *required* for inactivation, it would be expected that the initial rate would have been slower than the final rate The occurrence of a single critical site on a virus particle seems a bit improbable on purely intuitive grounds, and actually this type of curve does not exclude multiple attachment sites on a particle, as will be explained below.

From data on NDV neutralization (Rubin, 1957) and other sources, a likely model of neutralization is as follows: A virus particle has multiple attachment sites, and the number in the case of an NDV particle has been roughly estimated at 4 to 6 (Rubin, 1957) If a single antibody molecule adsorbs to an attachment site, the absorbing area is not entirely covered, at least functionally, and the virus may still attach to the host cell by means of this site, but since penetration and infection do not take place, such a particle is scored as neutral However, if several antibody molecules react with an attachment site, the area may be so covered that the virus can no longer adsorb to a host cell at this location Thus, each particle *may* be eliminated as an

detection and the identification of such components The term "soluble substance" is used to indicate viral products or by-products of virus growth which are smaller in size than the virus itself. They are often released by the virus-infected cell The soluble substances are quite different from one virus to another. In the case of vaccinia virus, the soluble substance is a protein which can be separated from the elementary virus particle without loss of virus viability while, in the case of influenza virus, it is a nucleoprotein which probably is completely covered in the intact particle but is produced in free form by infected cells Such substances can be detected and quantitated by serologic methods such as complement fixation

The antigens which make up the mature particle are manufactured by the infected cell as subunits which are later assembled into mature particles. By an elegant extension of conventional serologic methods, fluorescent antibody can be used to locate virus constituents in the infected cell before the final assembly has begun This is discussed in detail in the section on animal virus multiplication

Serologic tests may be used for fairly fine but usually not very precise comparisons of closely related but different virus strains It is widely recognized, for example, that the serologic properties of influenza A viruses differ from one outbreak to another By the use of serologic tests, a number of closely similar strains may be tested for their ability to react with a corresponding set of antisera Reciprocal tests can be set up between the strains and their antisera and, even if the differences are slight, each strain may show a higher affinity for its own antiserum The differences can be magnified by the use of cross-absorbed sera The small distinctions which can be made are useful, especially with influenza where naturally occurring minor modifications in the virus are common (Jensen, 1957) and important

HEMAGGLUTINATION

During recent years, it has been found that a wide variety of animal viruses are capable of *agglutinating red blood cells, and hemagglutination*, like serology, has become a useful tool in both the clinical and the experimental laboratory The first example of virus hemagglutination (Hirst, 1941; McClelland and Hare, 1941) was found accidentally in the course of work with allantoic fluid from chick embryos that had been infected with influenza virus Whenever allantoic fluid is casually removed from an egg, it becomes mixed with freshly shed embryonic blood, and this afforded an excellent opportunity to see the agglutination which takes place almost at once in those fluids that contain a great deal of virus It was found subsequently that this clumping was due to the direct action of the virus particle on the red cell, and similar examples involving other viruses soon followed The importance of hemagglutination is *broadly 2-fold*, *(1)* a technic for in vitro titration of viruses and antibodies, and (2) a model for host-virus interactions

The viruses which are known to cause hemagglutination fall into several well-defined groups, plus a number of miscellaneous and isolated examples:

1 [illegible]
are 2 [illegible]
plex [illegible]
vaccir [illegible]
[illegible]

only group in which the hemagglutinin is clearly and readily separable from the intact infectious virus particle

2 The arbor virus group This is made up of arthropod-borne viruses, such as the agents of Japanese B encephalitis (Sabin and Buescher, 1950), yellow fever, West Nile, dengue, St Louis and others (Casals and Brown, 1954) This group has been subdivided into 3 parts (A, B and C) on the basis of antigenic relationships as determined by the hemagglutination inhibition test (Chap. 12)

[illegible]

thetic group from certain mucoproteins, which is a reaction having a bearing on adsorption and possibly penetration

In summary then, neither animal nor bacterial viruses show much of a dissociation effect when tested by similar methods, and it is not necessary to invoke dissociation for most reactivation experiments on the dilution of animal virus-antibody mixtures.

The Persistent or Non-neutralizable Fraction. The phenomenon of the persistent virus fraction can be illustrated in the following experiment Different amounts of antibody (Fig 33) are added to a constant amount of poliomyelitis virus and, after a period of incubation, the surviving virus is measured by plague assay. With small amounts of antibody, the logarithm of the surviving virus fraction varied inversely with the serum concentration However, when the surviving fraction became less than 1 per cent, the addition of a large excess of antibody had no effect in decreasing it further This residue of active virus is known as the persistent or non-neutralizable fraction It also occurs with other

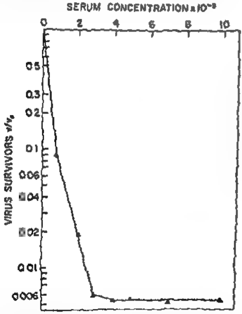

FIG. 33 Curve of neutralization of poliomyelitis virus, using different concentrations of serum and 4×10^7 plaque-forming units of virus Virus and serum stood for 2 hours before virus survivors were plated. (Dulbecco, et al, 1956, A study of the basic aspects of neutralization of two animal viruses, Western equine encephalitis virus and poliomyelitis virus, Virology 2, 162-205)

virus-antibody systems but is especially prominent with poliomyelitis virus

The following statements may be made about this fraction of virus: (1) It is not genetically different from the bulk of the virus in a preparation. Subculture of resistant virus does not give resistant virus (Dulbecco et al., 1956). (2) The virus particles are neutralizable. They do not have a different type of coat than the majority (Mandel, unpublished observations). (3). The persistent fraction seems to come from virus which has reacted with antibody and, after adsorption to the cell, penetrates slowly During this period of slow penetration the process of infection may be stopped if the virus reacts with more antibody or, if the already attached antibody dissociates, the virus may go ahead and infect (4) The persistent fraction is probably due to an equilibrium state between antibody, virus and antibody-virus complexes partly free and partly adsorbed to the cells

There are at least two stages in the adsorption of an animal virus to a host cell The first is characterized by loose binding, and the virus remains accessible to the neutralizing action of immune serum This goes rapidly into a second stage in which the adsorption is no longer reversible nor is it affected by serum The rate at which the virus goes from the first to the second stage is affected markedly by temperature The fact that antisera have no effect on viruses after an early stage of adsorption or penetration has important implications for the pathogenesis and the treatment of virus diseases Antisera may affect the ability of virus to move from one cell to another but cannot affect the issue in a cell already infected

In addition to antibodies directed at the virus particle it is also possible to work with antibodies directed at the host cell, especially in in vitro systems (Quersin-Thiry, 1955, Habel et al, 1958) This aspect of serology has as yet been explored very little but appears to be important Some anticell antibodies are capable of preventing infection with certain viruses but not with others.

Serologic Detection of Virus Antigens. Viruses are commonly made up of a number of macromolecular components which can often be fractionated by relatively simple procedures Serology is a useful tool for the

detection and the identification of such components The term "soluble substance" is used to indicate viral products or by-products of virus growth which are smaller in size than the virus itself. They are often released by the virus-infected cell. The soluble substances are quite different from one virus to another In the case of vaccinia virus, the soluble substance is a protein which can be separated from the elementary virus particle without loss of virus viability while, in the case of influenza virus, it is a nucleoprotein which probably is completely covered in the intact particle but is produced in free form by infected cells. Such substances can be detected and quantitated by serologic methods such as complement fixation.

The antigens which make up the mature particle are manufactured by the infected cell as subunits which are later assembled into mature particles. By an elegant extension of conventional serologic methods, fluorescent antibody can be used to locate virus constituents in the infected cell before the final assembly has begun This is discussed in detail in the section on animal virus multiplication

Serologic tests may be used for fairly fine but usually not very precise comparisons of closely related but different virus strains It is widely recognized, for example, that the serologic properties of influenza A viruses differ from one outbreak to another By the use of serologic tests, a number of closely similar strains may be tested for their ability to react with a corresponding set of antisera Reciprocal tests can be set up between the strains and their antisera and, even if the differences are slight, each strain may show a higher affinity for its own antiserum. The differences can be magnified by the use of cross-absorbed sera The small distinctions which can be made are useful, especially with influenza where naturally occurring minor modifications in the virus are common (Jensen, 1957) and important

HEMAGGLUTINATION

During recent years, it has been found that a wide variety of animal viruses are capable of agglutinating red blood cells, and hemagglutination, like serology, has become a useful tool in both the clinical and the experimental laboratory The first example of virus hemagglutination (Hirst, 1941; McClelland and Hare, 1941) was found accidentally in the course of work with allantoic fluid from chick embryos that had been infected with influenza virus Whenever allantoic fluid is casually removed from an egg, it becomes mixed with freshly shed embryonic blood, and this afforded an excellent opportunity to see the agglutination which takes place almost at once in those fluids that contain a great deal of virus It was found subsequently that this clumping was due to the direct action of the virus particle on the red cell, and similar examples involving other viruses soon followed The importance of hemagglutination is broadly 2-fold, (1) a technic for in vitro titration of viruses and antibodies, and (2) a model for host-virus interactions

The viruses which are known to cause hemagglutination fall into several well-defined groups, plus a number of miscellaneous and isolated examples

1 [illegible]
are 2 [illegible]
plex [illegible]
vaccin [illegible]
1944) ectromelia (Burnet and Boake, 1946) and (B) the psittacosis-lymphogranuloma venereum group of viruses including meningoencephalitis (Hilleman et al., 1951) and psittacosis (Gogolak and Ross, 1955) This is the only group in which the hemagglutinin is clearly and readily separable from the intact infectious virus particle

2. The arbor virus group This is made up of arthropod-borne viruses, such as the agents of Japanese B encephalitis (Sabin and Buescher, 1950), yellow fever, West Nile, dengue, St Louis and others (Casals and Brown, 1954) This group has been subdivided into 3 parts (A, B and C) on the basis of antigenic relationships as determined by the hemagglutination inhibition test (Chap 12)

3 The myxovirus group. This includes the viruses of influenza (subtypes A to D), mumps (Levens and Enders, 1945), Newcastle disease (Burnet, 1942) and fowl plague (Lush, 1943) This is the group of greatest general interest in virology because all members have an enzyme capable of splitting off a small prosthetic group from certain mucoproteins, which is a reaction having a bearing on adsorption and possibly penetration

4. Echo viruses and Coxsackie B_3 The occurrence of a fourth major group of viruses which cause hemagglutination has been described recently (Goldfield et al., 1957, Labelle, 1958) and includes a number of echo viruses (types 3, 6, 7, 10, 11 and 12) as well as Coxsackie B_3 The hemagglutinin is active against human O cells, and the reaction can be inhibited by strain-specific antisera Of greatest interest is the information, so far available only in preliminary form, that the hemagglutinin is part of the virus particle, and that the HA activity elutes from red cells after destruction of red cell receptors. A receptor gradient similar to that seen with myxoviruses was found, and the receptors for echo and myxoviruses are entirely different

5 Adenoviruses Agglutination of erythrocytes by adenoviruses has been described recently by Rosen (1958). More than 18 different types were tested against a variety of species of red cells and all but 3 agglutinated at least a species of cell The pattern in terms of the cell species agglutinated appeared to be specific for each virus type.

6. The miscellaneous group.

A. The encephalomyocarditis viruses (Hallauer, 1946; Ohtsky and Yager, 1949), including strains Columbia-SK, MM, EMC and Mengo These agents agglutinate only sheep cells

B Pneumonia virus of mice (Mills and Dochez, 1944, Curnen and Horsfall, 1947)

stable and dissociates from tissue inhibitors at high temperatures

C The GDVII strain of murine poliomyelitis (Labelle and Horsfall, 1949) This is the only known strain of this group which has a hemagglutinin It agglutinates human cells only at low temperatures

D Polyoma virus of mice (Eddy et al, 1958). This is an example of a tumor-inciting virus which agglutinates red cells of several mammalian species

Hemagglutination by Lipoproteins

A Pox viruses Vaccinia, variola and ectromelia all produce dermal vesicular infections, they are antigenically related, they are of similar size and constitution, being large and complex as viruses go, and they all have a hemagglutinin which is not an integral part of the virus The hemagglutinin can be separated readily from the virus, either by centrifugation or by absorption with susceptible red cells, and this can be done without significant loss of virus infectivity. Vaccinia

and Boake, 1946). Both of these hemagglutinins act alike in agglutinating the red cells of about one half of the ordinary domestic fowl Neither agglutinates chick embryo cells, and only ectromelia is active on mouse red cells.

The hemagglutinins of this group can be inactivated by the action of both the *B. welchii* alpha toxin and by cobra venom if these reagents are used under conditions where the lecithinase they contain is active (Stone, 1946). Purified mixtures of lipids also agglutinate the same fowl cells that are agglutinated by viral preparations. These bits of evidence point to the likelihood that the hemagglutinins are phospholipids The serologic specificity of ectromelia and vaccinia hemagglutinins makes it seem more likely that the molecule is complex, possibly a lipoprotein

There are quantitative differences in the amount of hemagglutinin produced in different hosts and, in infected calf skin, it appears to be absent, although this may be due to destruction by oxygen from the air (Stone and Burnet, 1946). Some strains of vaccinia do not produce a hemagglutinin, nor do animals infected with such strains produce antibodies against the hemagglutinin of other strains (Fenner, personal communication) Animals infected with hemagglutinating strains do produce antibodies against the hemagglutinin, and it has been shown that these are not neutralizing antibodies The function of the hemagglutinin in infection is not clear

B The psittacosis-lymphogranuloma venereum group. The viruses of this group are large and complex and, like the pox viruses, they tend to produce chronic low-grade infections and are susceptible to the action of antibiotics Of the viruses in this group, murine and feline pneumonitis, meningopneumonitis and psittacosis are known to possess a hemagglutinin. Only psittacosis virus (a single strain) has been studied in any detail (Gogolak and Ross, 1955). The results are strikingly similar to what was found with the pox viruses The active fraction is readily separable from the virus particles by simple centrifugation The hemagglutinin is active only against mouse cells The active material contains a lipoprotein from which a lipid may be extracted which agglutinates red cells but has

no serospecificity, while a nucleoprotein extracted from the same material has antigenic specificity but no action on red cells Lecithinases will destroy the hemagglutinating activity. Antiviral antibody specifically inhibits the hemagglutination reaction, but psittacosis and meningopneumonitis could not be differentiated by this method

Hemagglutination by Arthropod-Borne Viruses This group includes a number of small viruses which can multiply in vertebrate hosts and are also found in and may be transmitted by mosquitoes The hemagglutinins are usually prepared from the brains of young mice, and the extracts are most active on the red cells of newly hatched chicks The agglutination reaction must be carried out under rather sharply prescribed conditions It is inhibited readily by lipids and is very sensitive to slight changes in pH Few studies have been done on the hemagglutinin itself or its relationship to the virus particle The viruses which have this activity include many of the encephalitic agents: St Louis, Murray Valley, Japanese B, Western equine, Russian spring-summer and others The active group also includes the viruses of dengue and yellow fever, as well as a number of other agents that have been isolated directly from mosquitoes These agents differ from each other antigenically, and in neutralization tests the differences are frequently found to be large Antigenic disparity is somewhat less by the agglutination inhibition test and, on the basis of the latter, all of these viruses have been subdivided into 3 large fairly homogeneous groups (arbor A, B and C) (Casals, 1957)

Hemagglutination by Encephalomyocarditis Viruses The viruses of this group incl[illegible]

vir[illegible]

she[illegible]

from the red cell at high temperatures, and the red cell receptors are unaffected by contact with the virus. The attachment of virus to cells will not take place in the absence of calcium It has been reported that crude extracts (Verlinde et al, 1951) containing the receptor-destroying enzyme for the myxoviruses also act on receptors for this group, but there is scant evidence that the same

[illegible]

poliomyelitis virus (GDVII) is known to agglutinate red cells, though other closely allied and antigenically related strains have been tested. The GDVII strain agglutinates human red cells at low temperature but not at 37° C., where the virus dissociates from the receptor. The red cells thereafter are normal in appearance and are reagglutinable. The hemagglutinin is clearly part of the virus particle and is inhibited by antiserum A mucopolysaccharide found in mouse intestine (Mandel and Racker, 1953) has both a hemagglutinin inhibiting and a neutralizing effect on this strain The polysaccharide may be dissociated from the virus by changing the salt concentration, but the inhibitory action of the carbohydrate is not destroyed by the virus This mucopolysaccharide has no inhibitory effect on other viruses, such as those of the myxo group for example, but an intestinal virus combining with a polysaccharide overlying the host cells seems to be closely analogous to the influenza model A striking difference is the inability of GDVII to alter this polysaccharide in a detectable way

Hemagglutination by Pneumonia Virus of Mice (PVM) All virus strains known give the hemagglutinin reaction The virus agglutinates mouse and hamster cells The tissues of both these animals contain high levels of hemagglutinin inhibitor which combines rapidly with the virus, especially when an attempt is made to remove the agent from the lungs by grinding (Curnen and Horsfall, 1947, Curnen et al, 1947) The virus may be dissociated either from red cells or from tissue inhibitor by heating to 75° C. This temperature does not inactivate the hemagglutinin itself The hemagglutinin is part of the virus particle It is possible, though unproved, that the hemagglutinin represents an attachment mechanism operative in normal infection

Hemagglutination by Myxoviruses There are 4 different viruses in this group (influenza, mumps, NDV and fowl plague [FPV]), and all the strains tested have the capacity of splitting neuraminic acid derivatives from mucoproteins which are found in body fluids or on the surfaces of cells These agents differ very markedly in the kind of disease picture they produce in their normal hosts For a variety of reasons, they have become model agents for study of animal virus behavior, and they are described further under the section on virus multiplication.

The viruses of this group agglutinate a variety of red cells, both avian and mammalian Not all mammalian cells agglutinate equally well but, in practice, human, guinea pig or domestic fowl red cells are usually

used The agglutination of red cells occurs rapidly under physiologic conditions and, when the ratio "particles/red cells" is high, visible aggregation occurs within a few seconds. The occurrence of clumping is due to the formation of a lattice structure in which virus particles form bridges between red cells

Agglutination or adsorption of virus to cells requires the presence of electrolytes, and it occurs almost equally well over a wide range of hydrogen ion concentrations and at either zero or 37° C. A number of lines of evidence indicate that the hemagglutinin is part of the virus particle itself The number of attachment sites per virus particle is not known except that it must be 2 or more. From data on their enzymatic activity, it may be supposed that the virus sites are protein in character Red cell receptors are also multiple, they are mucoprotein in nature, and more than 1,000 virus particles may attach to a single cell

The clumping of red cells has been widely used in a test for the presence of virus Since the property of hemagglutination is more stable than that of infectivity, the hemagglutination titer gives a closer estimate of the number of particles than of the number of infectious units Of course, the sensitivity of the method does not compare with that of infectivity With a well-adapted laboratory strain, prepared in the best way, it requires of the order of 10^8 infective particles to cause ... con- ... ual 10 to 20 inactive particles for every infective particle, or about 10^7 particles per ml for visible agglutination Estimates of the number of hemagglutinating particles can also be made by counting the number of red cell dimers formed when red cells are present in excess of the virus Each dimer corresponds to 1 virus particle (Levine et al, 1953, Horsfall, 1954). Still another method for estimating particle number makes use of the adsorption to red cell ghosts A virus preparation is allowed to adsorb to ghosts and the number of adsorbed particles per ghost can be counted by electron microscopy (Dawson and Elford, 1949)

Hemagglutination can be inhibited by specific antibody directed at the virus. There is a considerable body of evidence that antibody which is antihemagglutinating is also neutralizing With influenza, there is a fairly close though not perfect correlation of inhibiting titer with neutralizing titer in a wide range of sera. The kinetics of neutralization follow very closely the kinetics of hemagglutination inhibition with NDV (Rubin, 1957). With influenza, both inhibition and neutralization show a high degree of strain specificity, in marked contrast with what is shown by the complement-fixation reaction However, absorption experiments indicate that the overlapping is not complete, and there is some antibody which neutralizes but does not inhibit (Walker and Horsfall, 1950) By and large, it appears that the sites by which a *virus attaches to a red cell are the same as* those through which it attaches to a host cell, and antibody which interferes with one operation will interfere with the other.

Operationally, the viruses of this group are distinguished from all others by the fact that they elute *spontaneously* after adsorption to red cells The cells that release virus after adsorption simultaneously lose virus receptors and, eventually, come to a state where they do not adsorb virus at all. On the other hand, the virus particles are capable of undergoing numerous adsorption-release cycles without detectable change There is now considerable evidence that the viruses of this group have an enzyme capable of destroying an essential part of the cell receptor, and this destruction is what permits elution to occur The nature of the enzymatic reaction is now known and is discussed in a later section

The Action of Viruses on the Red Cell. When influenza viruses are allowed to act on red cells until all the receptors are removed, there are no visible changes Virus action uncovers a new antigen on the red cell surface (Burnet and Anderson, 1947) The electrical charge of the cell changes markedly as receptor destruction continues (Hanig, 1948).

Studies on these changes in red cells were greatly facilitated by the discovery of an enzyme in bacterial filtrates (Burnet and Stone, 1947) which is like the virus enzyme of this group in that it destroys cellular virus receptors The enzyme is widespread in the bacterial world and is commonly prepared from *V. cholerae.* The discovery of this receptor-destroying enzyme (*RDE*) proved to be especially important in studying the receptor gradient and the influence of receptor destruction on infection of cells

The Receptor Gradient. When red cells are treated with the bacterial enzyme RDE,

TABLE 6

− = no agglutination

+ = partial agglutination

++ = full agglutination

The electrophoretic mobilities of the cells after treatment (from Ada and Stone, 1950) are shown on the right.

virus receptors are gradually removed and, after a time, the cells will no longer be agglutinable by any of the myxoviruses. When the agglutinability of cells is tested with a number of myxoviruses during the course of RDE treatment, it is found that they lose their ability to be clumped by (or to adsorb some of the viruses long before their reaction with other viruses is much affected. The order in which the viruses lose agglutinating power is called the receptor gradient (Burnet, 1942, 1955) (Table 6). The same gradient may be demonstrated by using some of the viruses to remove receptors. Strain *Swine*, for example, which is far down the gradient and agglutinates RDE-treated cells after most other strains fail, is also a potent virus in removing all of the receptors. Other strains in the gradient series are less vigorous and, in general, will abolish receptors only for themselves and for those viruses which are higher in the gradient. When very large amounts of virus are used in treating red cells and the incubation is carried out over a long period of time, all receptors may be removed, even by a virus high in the series (Hirst, 1950).

The removal of receptors from red cells, either by viruses or by RDE, is accompanied by a marked change in the electrophoretic mobility of the cells (Hanig, 1948). In general, it is found that the change in mobility and receptor removal run parallel. Using RDE to remove receptors, it is possible to determine the mobility of cells at the stages when agglutinability for various viruses disappears (Ada and Stone, 1950, Stone and Ada, 1950, 1952). The same parameters can be followed when various viruses are used for removing receptors. In general, it has been found that those strains that remove few receptors can change the mobility relatively little, and vice versa (Table 6). However, the mobility at which agglutinability with a given virus ceases is variable, depending on what agent is used to remove receptors. Other anomalies are also found. For example, Mel virus removes mumps receptors early, before the cell mobility is greatly lowered, while RDE does not remove them until the cell mobility is very low.

A satisfactory explanation of the receptor gradient obviously involves complexities of virus and cell structure with which we are not yet able to cope. Two general approaches to an explanation have been offered: (1) The first hypothesis involves the assumption that there are at least several different kinds of receptor spots and several kinds of virus enzymes. The gradient would be due to the presence of different arrays of these enzymes

used The agglutination of red cells occurs rapidly under physiologic conditions and, when the ratio "particles/red cells" is high, visible aggregation occurs within a few seconds The occurrence of clumping is due to the formation of a lattice structure in which virus particles form bridges between red cells

Agglutination or adsorption of virus to cells requires the presence of electrolytes, and it occurs almost equally well over a wide range of hydrogen ion concentrations and at either zero or 37° C. The cells were exhaustively treated with the viruses shown on the left and then tested for agglutinability by the viruses shown at the top

− = no agglutination

\+ = partial agglutination

++ = full agglutination

The electrophoretic mobilities of the cells after treatment (from Ada and Stone, 1950) are shown on the right

virus receptors are gradually removed and, after a time, the cells will no longer be agglutinable by any of the myxoviruses When the agglutinability of cells is tested with a number of myxoviruses during the course of RDE treatment, it is found that they lose their ability to be clumped by (or to adsorb some of the viruses long before their reaction with other viruses is much affected The order in which the viruses lose agglutinating power is called the receptor gradient (Burnet, 1942, 1955) (Table 6). The same gradient may be demonstrated by using some of the viruses to remove receptors Strain *Swine*, for example, which is far down the gradient and agglutinates RDE-treated cells after most other strains fail, is also a potent virus in removing all of the receptors Other strains in the gradient series are less vigorous and, in general, will abolish receptors only for themselves and for those viruses which are higher in the gradient When very large amounts of virus are used in treating red cells and the incubation is carried out over a long period of time, all receptors may be removed, even by a virus high in the series (Hirst, 1950)

The removal of receptors from red cells, either by viruses or by RDE, is accompanied by a marked change in the electrophoretic mobility of the cells (Hanig, 1948) In general, it is found that the change in mobility and receptor removal run parallel Using RDE to remove receptors, it is possible to determine the mobility of cells at the stages when agglutinability for various viruses disappears (Ada and Stone, 1950, Stone and Ada, 1950, 1952) The same parameters can be followed when various viruses are used for removing receptors In general, it has been found that those strains that remove few receptors can change the mobility relatively little, and vice versa (Table 6) However, the mobility at which agglutinability with a given virus ceases is variable, depending on what agent is used to remove receptors Other anomalies are also found For example, Mel virus removes mumps receptors early, before the cell mobility is greatly lowered, while RDE does not remove them until the cell mobility is very low

A satisfactory explanation of the receptor gradient obviously involves complexities of virus and cell structure with which we are not yet able to cope Two general approaches to an explanation have been offered (1) The first hypothesis involves the assumption that there are at least several different kinds of receptor spots and several kinds of virus enzymes The gradient would be due to the presence of different arrays of these enzymes

on different viruses Just from the data in Table 6, it appears that the number of qualitatively different receptors might have to be rather large, and the main difficulty with this approach is that independent evidence for this multiplicity of enzymes and receptors is lacking. (2) The second hypothesis assumes that the red cell receptors are qualitatively similar but vary in their accessibility to enzyme action In this case, the viruses would differ in their ability to lyse the less accessible groups This theory has an *ad hoc* quality which is not very satisfying, besides which it does nothing to explain all the anomalies of agglutination and mobility

Removal of NDV Receptors. It seems reasonably clear that the forces which bind virus and red cell together are in some way related to an enzyme-substrate combination, and when the substrate is altered the binding force disappears, and virus enzyme and substrate separate It was first shown clearly by Sagik et al (1954) that one virus particle could remove all of the receptors from a cell without separation at any time The results suggest that the particle is adsorbed to the cell at several sites simultaneously and, as one receptor is lysed, the virus rolls around until it makes contact at another point This process is continued until all available receptors are used up This method of receptor destruction (sometimes called browsing) is doubtless more efficient than a process wherein virus becomes fully detached after each enzyme-substrate reaction It seems possible, though unproved, that the cessation of receptor lysis found by Stone and Ada may have coincided with the end of lysis by browsing and that the receptors remaining thereafter were removed at a much slower rate (Hirst, 1950), one receptor per attachment.

Hemolysis. One other change which sometimes goes with the action of viruses of this group on red cells is hemolysis. Both mumps and NDV cause partial hemolysis of cells, but it may well be that this is due to a system apart from that causing receptor destruction. All the evidence indicates that it is necessary for the virus to be attached to the cell by the regular receptor sites in order for hemolysis to occur. Preliminary destruction of red cell receptors, either by RDE or by influenza viruses, prevents lysis by mumps and NDV (Burnet and Lind, 1950; Chu and Morgan, 1950).

Agglutination by Freshly Isolated Influenza Virus. When some strains of influenza virus are first isolated from the human respiratory tract (Burnet and Bull, 1943) by inoculation of the amniotic sac, it is found that the infected amniotic fluid agglutinates guinea pig (or human) red cells to high titer but does not agglutinate chicken red cells, or at least the titer is low. After a single further passage in the allantoic sac of chick embryos, the virus is capable of agglutinating *both* kinds of cells to high titer, and this is the usual form (D or derivative) of most laboratory strains If the virus is passed in human embryonic cells (Mogabgab et al, 1954), it may remain in the O form This can also be done in the amniotic sac with some care Studies suggest that the D form is a mutant which is selectively favored with growth in the allantoic sac and suppressed somewhat in human host cells, but the physiologic significance of the altered agglutination pattern is not known

Hemagglutination Inhibitors. Ever since the enzymatic nature of receptor destruction was suggested, the elucidation of the chemical nature of the reaction has been a challenge No real progress toward this end was made as long as the substrate being studied remained part of a large cell A crucial step in further progress was the discovery that influenza virus could be heated in such a way that it retained its ability to attach to receptors and agglutinate red cells but lost its power to destroy receptors and elute from cells (Francis, 1947) The virus behaved very much as if it had retained much of the receptor configuration but had lost some part of the enzymatic mechanism With this type of virus, it was discovered that substances were present in many body fluids and secretions (Anderson, 1948) which also (like red cell receptors) combined with heated virus irreversibly so that the virus could no longer agglutinate red cells It was suspected and confirmed that these substances were analogous to the surface material of red cells responsible for virus attachment. Unheated virus, for example, could destroy the effect of these soluble inhibitors. A soluble inhibitor

has been extracted from red cells (Howe et al., 1957).

These substances which gave inhibition came from a variety of sources secretory glands such as the salivary or parotid, ovarian cysts, egg white, serum, urine, tissue extracts and others In every case where it has been sufficiently investigated, the inhibitory substance has proved to be a mucoprotein Mucoproteins are a class of compounds in which a protein moiety is coupled with a large number of polysaccharide units. They are notoriously difficult to purify, and one of the best sources of pure inhibitor has been from urine where there are relatively few other proteins (Tamm and Horsfall, 1950)

In every case that has been examined, the action of either RDE or one of the myxoviruses on inhibitors has resulted in the loss of inhibitory capacity and also in the release of small molecular weight compounds which include N-acetyl neuraminic acid (NANA) other similar reducing sugars and amino acids (Gottschalk, 1957). From cow colostrum a trisaccharide (neuramin lactose) has been isolated and from partial degradation of natural mucoidal HA inhibitors N-acetyl chondrosamine has been obtained as a disaccharide Neither of these compounds is an inhibitor but the virus releases NANA from both of them In the former, the NANA is believed to be attached to the hydroxyl group of galactose and, in the latter possibly to the nitrogen of the chondrosamine Gottschalk has suggested that the enzyme hydrolytically cleaves a glycosidic linkage joining the keto group of neuraminic acid to the H group of galactose or the nitrogen of chondrosamine This very exciting demonstration of the chemical action of a virus enzyme doubtless will lead in time to a deeper understanding of the agglutination process and the role of the enzyme in infection. The liberation of amino acids and other reducing substances from mucoids by virus action, as well as the complexities of the receptor gradient, strongly suggest that other virus enzymes and substrates may be involved in the destruction of receptors and inhibitors

In spite of the extent that viruses have been studied, very few intrinsic enzymes have been found. It is now widely assumed that, in their extracellular form, viruses do not contain any metabolic enzymes An ATPase has been found in preparations of avian erythroblastosis virus (Beard et al, 1955) and is believed to be part of the virus particle Enzymes which have been extracted from the tail of phage particles are able to attack the bacterial membrane (Kozloff et al, 1957; Weidel and Primosigh, 1957) Some bacteriophages which attack Friedlander's bacillus carry a specific hydrolytic enzyme which attacks the bacterial capsular substance (Adams and Park, 1956) and may assist the virus in clearing a path for attachment to the cell wall Phage-induced enzymes capable of cell lysis have also been found (Murphy, 1957)

FUNCTIONAL SIGNIFICANCE OF THE RECEPTOR-DESTROYING SYSTEM

It is somewhat paradoxical that more is now known about the chemical nature of the myxovirus enzyme-receptor system than about its functional significance for virus infection. It seems almost certain that it has a function, since all viruses of this group possess the enzyme, and all known host cells have lysable receptors

If it were not for the occurrence of receptors and the attachment system of viruses that goes with it, it is very likely that infection would not take place or that the efficiency of infection would be greatly reduced When host cells (mouse lung chorio-allantoic membrane or tissue culture preparations) are treated with RDE, infective virus no longer attaches very successfully and the probability of infection by virus is reduced sharply (Stone, 1948) In the living egg, receptors can regenerate with time, and the tissues resume their normal susceptibility All these facts indicate that intact receptors are either necessary or at least very helpful in bringing about infection While it seems logical that the next step after attachment would involve destruction of the receptor and penetration there is no direct evidence supporting this assumption Experiments have been described which purport to show that virus can enter the cell in the face of receptors which are resistant to lysis, but these experiments are not very convincing It has also been suggested (on the hypothesis that a drug, AMPS,

is a specific inhibitor of the virus enzyme) that the virus needs the enzyme for final separation from the cell after maturation as well as for initial penetration (Ackermann and Francis, 1954) It is also possible that the enzyme ■ necessary for some intracellular function Still another possibility is that the respiratory mucosa is covered by substances, *including mucoproteins, which attract and* bind influenza virus (such as the intestinal polysaccharide which binds mouse poliovirus [Mandel and Racker, 1953]) and would prevent it from infecting respiratory cells if it were not for the enzymatic ability of the virus which enables it to destroy this "defense" mechanism

In summary, hemagglutination has a wide distribution in the animal virus world With most viruses, however, the reaction between virus and red cells is an adsorption, dependent on electrolytes, often dissociated at high temperatures, specifically inhibited by viral antisera, but which has told us very little so far about virus-cell interactions which occur on infection Only *with the myxoviruses, where* the red cell-virus interaction is clearly analogous to host cell-virus interaction, has the study of the reaction given evidence which applies to the initiation of the infective cycle

VIRUS MULTIPLICATION

Viral multiplication is strictly intracellular Hence, we must consider as its essential process the production of viral materials within virus-infected or virus-carrying cells this process ■ generally only observable insofar as it culminates in the production of infectious virus *It is most easily studied when it does* so within a relatively brief span, within the very cell that has been infected . Even then, however, viral multiplication is a process radically different from the multiplication of cellular organisms, whether free living ones or intracellular parasites. The dependence on the host is . not purely a nutritional one, as for other parasites, but an integrative one We may speak of viral multiplication as *viral biosynthesis, in the* same sense as we speak of the biosynthesis of macromolecular cellular constituents and organelles This viewpoint need not rob viruses of their "independence," but interprets it as a genetic and evolutionary independence, limited by the demands and the implications of the integration process within the host cell (quoted from Luria, 1958).

In the sections which follow, the process of virus infection and multiplication is described for representative strains of bacterial, animal and plant viruses. These events will be considered in terms of the following steps: adsorption, penetration, change to the noninfective form, replication of virus subunits, assembly of subunits or maturation, extrusion and cell lysis The description is in terms of model viruses in each case, noting exceptions with other material where the facts are clear

Multiplication of bacterial viruses is discussed briefly, and for comparative purposes. The discussion and references are covered much more adequately in Chapter 7

Multiplication of Bacterial Viruses

The model system has been 7 coliphages (T series), all of which lyse a single strain of *E coli*, strain B (Luria, 1953). The phages are polygonal in shape and have tails of varying length, dependent on the strain. The polygonal head consists mainly of DNA and is surrounded by a protein membrane. The tail is also of protein and is different from that which envelops the head

Phages attach to the host bacterium by the *tip of the tail The bacterial site of attachment* is very specific and is a substance under the genetic control of the organism. The configuration of this site is subject to change by mutation, following which the phage will no longer attach and can no longer infect It ■ technically easy to obtain a variety of resistant bacterial mutants

The initial attachment of virus to host occurs after random contact and is a loose and reversible adsorption (Tolmach, 1957) This stage is followed rapidly by a reorientation of the virus to a more specific and irreversible attachment For both these stages there are minimal and specific electrolyte requirements For some phages other cofactors are also required for firm attachment (Stent and Wollman, 1950), of which the most efficient is 5-methyl-tryptophane. Following oriented attachment there is some hydrolysis of the bacterial membrane (Kozloff et al, 1957), and the injection mechanism is triggered so that the DNA content of the phage head is in-

jected into the bacterium An empty protein bag is left outside the cell and may be removed mechanically without altering the course of the intracellular infection (Hershey and Chase, 1952). This special device for infecting a cell is seen only with bacterial viruses and probably was necessitated by the rigid membrane which surrounds these cells It is interesting that, when the structure of the virus is injured, the particles are unable to infect bacterial cells unless the membrane is removed (Fraser et al., 1957)

After the infecting phage has injected its DNA, the cells may be broken open, and no infectious particles are found, confirming the observation that the entire virus particle does not enter the cell (Doermann, 1952, 1953) This is called the eclipse phase and lasts about 10 minutes with some strains If the cells are broken open at intervals after the eclipse phase, an increasing number of mature (infectious) particles are found The number increases linearly with time until the host cell bursts A burst may contain 30 to several hundred particles, depending on the virus strain During the latent period, a series of processes are going on, resulting in the replication of phage subunits which are assembled later into finished particles

In many cases, when phages are first absorbed the cell is killed, at least in the sense that it does not divide With the injection of virus DNA, the bacterial nuclei begin to disintegrate with margination of chromatin (Luria and Human, 1950) However, the over-all metabolism of the cell is unchanged (Cohen, 1947, 1949) in terms of respiration, glucose and phosphate uptake The energy-mobilizing apparatus appears to be intact but there are extensive changes in the specific tasks which are being carried out Synthesis of *bacterial* DNA, RNA and protein cease abruptly, but synthesis of viral protein and of viral DNA begin Head and tail proteins appear in the cell before mature particles are seen by electron microscopy and at a time when DNA strands (Kellenberger and Séchaud, 1957) can be seen in the cell Finally, mature particles appear

The biochemical evidence indicates that the synthetic capabilities of a cell remain intact at the level of energy mobilization, but the control of what is synthesized is shifted abruptly from guidance by bacterial DNA to virus DNA While this new activity is directed especially toward the manufacture of macromolecules, the shift also occurs at levels of synthesis of smaller elements Examples are the induction of thymine synthesis by phage infection of a thymineless mutant of *E. coli* or the induction of hydroxymethylcytosine synthesis by T_2 infection (Cohen, 1953, 1957). Except for the small contribution of the DNA of infecting virus, there are no large molecular weight precursors of phage DNA or protein which are incorporated as such from bacterial sources It is this sort of evidence which has disposed of the once widely held notion that virus production was the result of slight changes in pre-existent cell subunits

Relatively little is known of the mechanics of the assembly of phage from its basic subunits. Proflavine will prevent this maturation causing a yield of empty head membranes (DeMars et al., 1953, Levinthal and Fisher, 1952) These protein membranes are antigenically quite distinct from the tail proteins It is the protein antigens of the tail, at least those of the tail tip, which carry the host range specificity of the phage These tail antigens are controlled by a number of genetic factors When infection of a bacterium takes place with two related phages which have different tail antigens (labelled "A" and "B" here for illustration), then progeny particles can be found which have "A" tails but are genetically "B" i e, the progeny of the next generation would have "B" tails Other particles have "B" tails but are "A" genotypes, and mixed "A-B" tails can also commonly be found in particles that have the genotype either "A" or "B" (Streisinger, 1956a, b) These results indicate that tail proteins may be formed under the direct control of each of several phages present in the same cell, but the various proteins that are made are used more or less at random in the assembly of phage particles This is another consequence of the loss of identity of the phage particle during this vegetative phase and it may be re-emphasized by stating that the DNA of a single phage particle does not preside over the manufacture of its own body and tail protein, but DNA and coat manufacture probably take place in different sites in the cell, and

the assembly of these subunits is fairly random

At the end of the maturation process the cell bursts, releasing phage particles, and the burst size is characteristic of the particular type of cell and virus, the state of bacterial nutrition and other factors, and ranges from 30 to several hundred. The burst may be brought about by an enzyme made under the direction of the virus and, under abnormal conditions, cell lysis may occur even when no mature particles are formed. Bacterial cells can also be lysed by exposing them to large amounts of virus In this case, the viruses do not get into the cell, and the mechanism of lysis is poorly understood.

In recent years, the development of the subject of phage genetics (Hershey and Rotman, 1949, Hershey and Chase, 1951) has done more than any other aspect of virology to revolutionize concepts concerning the nature of viruses Besides developing the methods of virus inheritance it has shed light on the whole problem of virus replication in the cell and has now gone much farther in contributing to and extending classic genetics and establishing a close link between DNA and inheritance For some aspects of genetic work, phage has proved to be the most favorable material

In the course of phage multiplication in host cells, virus mutations appear spontaneously and at random, affecting a number of viral properties Mutations affecting host range and the plaque type are readily recognized and have been studied most fully. Many mutants are quite stable and breed true Two sublines of the same virus stock may be obtained by selection of mutants, which differ from each other in respect to a number of known characters When a single bacterium is infected with these two strains (marked "ABC" and "abc" for example), the burst will contain a variety of progeny Some will be identical with one or the other parent, but some will have various combinations of characters, part from each of the two parents (e.g., "Abc," "ABc," "aBC," etc). The latter are called recombinants, and their occurrence indicates a sexual process in the production of phage. In classic genetic terms the virus is haploid, i e., it contains one set of genes. It has a single chromosome. As in the recombination between linked genes by crossing over in higher forms, the frequency of phage recombination is an indication of how far apart two genes are on the phage chromosome The phage chromosome may be mapped by the frequency of recombination, and map distances are additive, as in classic genetics

In some other respects phage genetics is not classic. In a cross involving two factors, the number of two reciprocal recombinants in the yield from a single cell is often not equal If three suitably marked phages are introduced into a single cell, one finds progeny with markers from all three parents, indicating that the reproductive process involves a number of rounds of mating Such an experiment shows that the infection of a bacterium with two agents does not produce a cross, as in classic genetic work, but is instead a population experiment (Visconti and Delbruck, 1953) The DNA from infecting organisms goes into a pool in the host bacterium where it is replicated Apparently, the replication process requires the pairing of two chromosomal structures for the formation of each daughter replica If the two structures come from different parents, there is a "copy choice" mechanism which enables the daughter to begin replicating one chromosome and finish with the other chromosome, thus enabling recombinants to occur Once such a replica is formed, it too can act as the pattern for still other replicas As particles are finished or mature, these chromosomal structures are withdrawn from the mating pool and, once coated, they become inert in the infected cell and do not re-enter the mating pool.

Studies of temperate viruses and lysogeny are covered in connection with the discussion on latency and tumor viruses.

Multiplication of Animal Viruses

The development of knowledge and technic in the animal virus field reflects very closely the discovery and the use of new host material, and we shall review the history of this branch of virology very briefly from this viewpoint. All technics for virus detection depend in the first instance on the demonstration of a pathologic condition, caused by the agent Later, other methods of virus detection may be used. The difficulty of establish-

ing a virus infection in a new host species is often formidable, and progress is often slow.

In the early part of the century, the main host was the rabbit. Inoculations were made into the brain (herpes), onto the cornea (variola), or into the skin (vaccinia). Monkeys were used for poliomyelitis, measles and yellow fever. In such animals, a quantitative approach to virology was all but impossible. Attention was focused on lesions, both gross and microscopic, and the study and the search for inclusion bodies was one of the main approaches and was important in diagnosis.

In the early 1930's, the use of the mouse and especially the intracerebral route of inoculation brought great changes. This animal provided not only a medium for cultivation [illegible]

new viruses of uncertain host range, many of which came from mosquitoes. In addition, the mouse provided a much more practical method of virus quantitation than existed before. At about this time the domestic ferret, then [illegible] for dog distemper work, proved to [illegible]

was not an important means of isolating new [illegible]

worked out in this species. In the use of mice, death was frequently used as the criterion of determining whether or not infection had occurred. The practice of examining the infected organ or looking at infected cells microscopically fell into discard, and newer virologists often did not know what inclusion bodies looked like.

Almost concomitant with the introduction of the mouse was the beginning employment [illegible]

tended by Burnet (Beveridge and Burnet, 1946). The embryonated egg provided [illegible]

bacteria and contaminating viruses. The absence of antibody production in the embryo was still another advantage. The formation of pocks on the chorio-allantoic membrane by vaccinia, herpes and other viruses provided the earliest means of enumerating animal virus particles. Some agents killed the embryo and were detected in that fashion [illegible]

new agents were first isolated and detected by any chick embryo technic alone.

The use of the chick embryo was a step forward, though not an especially large one, in the direction of a more quantitative approach to virology. Technics such as de-embryonation were developed in which the chorio-allantoic membrane alone was used for virus growth, but virus quantitation was still essentially on a basis of using widely spaced dilutions (3- to 10-fold) in large numbers of eggs, and the inaccuracies of titration were large. One of the reasons for the ability of many viruses to grow in the chick embryo is because it is an embryonic tissue. In this connection, the use of baby mice (Dalldorf and Sickles, 1948) for the isolation of intestinal viruses is also an example of exploiting the remaining embryonic potentialities of the cells of the newborn. A large number of viruses were isolated from the intestinal tract by this technic, and this was the first of several examples of the discovery of innocuous or latent viruses in human beings in great numbers.

The currently common technic for virus study involves tissue culture. Actually, tissue culture of a sort had been in use for many years, but the Maitland culture usually involved the infection of pieces of tissue surviving in vitro. These pieces of tissue supported the growth of a great variety of viruses, but infection was not usually accompanied by gross changes, and such methods were not much more advantageous than in vivo technics.

Following World War II, there were striking technologic advances in the culture of tissue cells in vitro. A variety of cells were cultivated on glass, and a real revolution in virologic practice was started when Enders and collaborators (Weller et al., 1949, Robbins et al., 1951) demonstrated that a wide variety of human and monkey cells, grown in vitro, would not only support the growth of poliomyelitis virus but also developed gross morphologic changes as well. This had the immediate effect, for example, of changing

poliomyelitis from one of the most difficult to one of the most accessible viruses for study Furthermore, cells cultivated in vitro had a wider range of virus susceptibility than their in vivo counterparts, and a number of new and "difficult" viruses became available for study (herpes zoster, varicella, measles, adenoviruses) The new technic also revealed a wealth of new latent agents (in cells of cultured kidneys and tonsils), the presence of which had not been suspected previously However, perhaps the most important single consequence has been the development of new methods for the enumeration of virus particles, as reviewed below.

Progress in all branches of science is dependent to a large extent on the technics available, and an increase in the accuracy of virus quantitation is bound to have a very marked effect on the quality of research with viruses The most common method of animal virus titration in the past has been one involving inoculation of serial dilutions of virus, each into a large number of animals The end point in such titrations was taken as the dilution (either directly tested or interpolated) of virus which caused half of the injected animals to die or show symptoms This type of test is described in detail elsewhere in this volume, and it will suffice to say here that it is often a poor method of quantitation because it is very inaccurate It is very difficult to bring the titration error below 100 per cent, and it is usually higher Essentially, this means that any effect being studied by titration had to be correspondingly large

In the past few years, virus particle enumeration technics have been devised which involve the formation of plaques in vitro in a manner quite analogous to the technic used for bacterial viruses (Dulbecco, 1952) Advances in tissue culture technic make it possible to grow sheets of cells on glass. For this purpose, either pure line cancer cells (HeLa) or so-called normal cells, or mixtures of cell types from trypsin-digested organs (kidney, whole chick embryos, amniotic membrane, etc.) are used, the choice being influenced by the tropisms of the virus to be tested. Such cells can form a continuous solid sheet, firmly attached to the bottom of a petri dish The virus to be tested, suspended in a small fluid volume, is incubated with the cells long enough for the virus particles to attach The unadsorbed virus is washed off, and the cells are overlaid with nutrient agar. Upon incubation, the cells which have been infected will yield or excrete virus, and the agar limits the spread of the infection to the neighboring cells, which yield virus in turn. Eventually, a small circular area of necrosis appears A vital dye (neutral red) applied to the plate is absorbed by living cells and increases the contrast between infected and uninfected areas. This method allows one to count viable virus particles with a high degree of accuracy and reproducibility Plaques are started by a single virus particle, and this makes it possible to isolate pure line cultures readily

While each plaque starts originally with the infection of a cell by a single particle, nevertheless, all particles in a virus suspension do not start plaques The reasons for this are several Many of the particles in a virus preparation may be inactive or defective Active particles may be adsorbed to cells at sites where they cannot go on and infect (abortive adsorption). Active particles in the inoculum may fail, just by chance, to come in proper contact with susceptible host cells during the adsorptive period These factors, especially that of inactive virus, are discussed further below Older technics, such as pock formation on the chorio-allantoic membrane, are operationally similar to plaque formation, but practically only vaccinia and Rous sarcoma virus give very reproducible results The use of hemagglutination as a means of estimating virus quantitatively has been mentioned already

The problem of presenting a coherent picture of the adsorption, the penetration and the multiplication of animal viruses is complicated by incomplete knowledge of many species This difficulty is made more acute by the gross differences of many animal viruses from each other, so that the adequacy of the model approach may be correctly questioned However, the state of existing knowledge virtually forces the use of a model system at the present time For this purpose we shall use the myxovirus group, including influenza, Newcastle disease (NDV), mumps and fowl plague (FPV) as illustrative material. This group is fairly homogeneous, and a certain amount of generalization from data on one

virus is permissible within the group These agents have already been described to some extent in the section on virus hemagglutination.

Viruses of the myxo group are nearly round in shape and, in cut sections, they are from ... (Morgan et al 1956) in diam- ... ed out, ... prep- ... me in- ... entous ... fluenza ... out 0 9 ... 1957) ... chafer, 1957). None ... DNA They contain about 30 per cent lipid, 3 5 per cent carbohydrate, and the remainder is protein (Ada, 1957, Frisch-Niggemeyer and Hoyle, 1956, Schafer, 1957) The carbohydrate may be the same as host cell carbohydrate (Ada and Gottschalk, 1956) As noted above, all members of this group are able to agglutinate red cells and to destroy red cell receptors

The virus particles of influenza and FPV ... e ... h ... ether to remove the lipid fraction, which also contains carbohydrate and protein There- ... ill be found which ...

HA substance

The S antigen ■ small, 10 to 15 mμ. and from FPV it contains 10 to 15 per cent RNA That from influenza also contains the entire RNA of the intact particle The specificity of the S substance is that of a group antigen Antisera that react with influenza S substance give a strong cross-reaction with FPV S substance Serologic and other data indicate that the S substance in the intact particle is completely covered Antibody against the S substance has no neutralizing effect, for example, S substance is found outside of particles in the infected cell, and many infected cells produce an excess of a substance which is indistinguishable from the S extracted from the virus

The HA substance agglutinates red cells, and this carries the same specificity as the virus particle It reacts with neutralizing serum A specific HA serum does not react with S particles

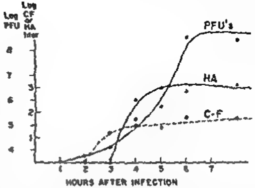

FIG 34 Graph after Breitenfeld and Schafer (1957), showing the rise in titer of complement-fixing (S) and hemagglutinating (HA) antigen in cells infected with fowl plague virus (FPV) The yield of plaque-forming particles is also shown Compare these results with those shown in Figures 35 and 36 where fluorescent antibody was used to detect these antigens.

There may be other antigens present in the virus, some of them possibly host antigens but so far they have not been differentiated

Adsorption and Penetration. How an animal virus gets into a cell is not yet known The membrane of an animal cell does not present the formidable barrier of the bacterial cell wall, and there is nothing about the morphology of animal viruses which suggests that the injection mechanism of phage is operative Viruses of this group, in general, adsorb rapidly to their host cells NDV has been shown to require electrolyte for attachment (Levine and Sagik, 1956) During the earliest phase of adsorption the virus is still accessible to antibody, and this initial phase ■ followed by penetration, which is a process that is highly temperature-dependent With penetra- ...

host cells has not been worked out in detail They are capable of infecting a variety of tissues in a variety of animals Cells in tissue culture are, in general, more susceptible to infection than those in the intact organism There is no doubt that the tropisms of these viruses and of animal viruses in general are much broader than those of bacterial viruses

These are pictures of fibroblasts that were infected with fowl plague virus (FPV) and stained with fluorescent antibody after varying intervals Some were stained for S antigen and some for HA antigen. The S antigen was not present at 2 hours but was plentiful in the nuclei at 3 hours Even at 10 hours (Fig 36), the nucleus contained more antigen than the cytoplasm (Breitenfeld and Schafer, 1957). The HA antigen was absent at 3 hours but, when it appeared at 4 hours, the cytoplasmic concentration was already high The bright spots seen at 4, 5 and 6 hours are unexplained—they are extranuclear At 14 hours, the HA antigen can be seen to be concentrated in the periphery of the cell (see Figs 34 and 37)

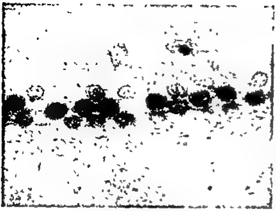

FIG 37. An electron microscope picture of a section through a chorio-allantoic cell infected with influenza virus The virus particles are organized units seen only in the cell wall The structure of the influenzal particles can be seen much better, and those at the lower limit of the membrane are more hazy in outline, suggesting incomplete maturation. (Morgan, et al, 1956, Structure and development of viruses observed in the electron microscope. III. Influenza virus J Exper Med *104*, 171-182)

Adsorption to cells is not always followed by penetration and infection In some cases, it seems that the virus has difficulty in going from the reversible to the irreversible stage of adsorption. This abortive adsorption may be more common with cells which are relatively resistant to infection

Penetration itself is not understood As stated in a previous section, the virus is adsorbed to receptor sites, and there is a virus enzyme available for lysing the site, but there is no direct evidence to indicate that such lysis actually does take place or is necessary. The number of attachment sites on a cell (if a red cell is used as a model) has been estimated as low as 300 (Sagik et al, 1954), though electron microscopy indicates a figure in the thousands (Isaacs, 1957) Whether all or only part of the virus goes into the cell is not known While the penetration of myxoviruses may proceed in a specific fashion, the infection of cells by defective (phenol-treated RNAase-sensitive) particles of poliomyelitis, for example (Colter et al, 1957), suggests that there may be some nonspecific method of virus entry.

The Eclipse Period. Following adsorption and penetration, there is a period when most of the adsorbed virus cannot be recovered as infective virus. At least 90 per cent becomes noninfective in the sense that it cannot be recovered from broken cells However, the recoverable active virus remains active and appears to be virus that has adsorbed to the cells in such a way that some but not all is elutable by RDE. Some is accessible to antibody and some not (Rubin et al, 1957) During the eclipse phase, the number of such particles may decrease somewhat, and it seems unlikely that they multiply. This small persistent active fraction and the disappearance of the majority of adsorbed virus is typical of a great many animal virus infections.

The important sequence of events during this latent period has been studied with both influenza and FPV, and the latter will be recounted in some detail If cells are infected with FPV (Breitenfeld and Schafer, 1957), there is a residual infective titer of about $10^{3.5}$ as shown in Figure 34

If aliquots of these infected cells are broken open at various intervals and examined for infective virus, S antigen (by complement fixation) and HA antigen (by hemagglutination), it is found that the S antigen appears first 3 hours after infection (Fig 34) and before there has been a significant rise in infective titer. Likewise, the HA titer goes up at 4 hours, just before infective virus appears Even more striking, however, is the examination of these cells with specific fluorescent antibody for the S and HA antigens in the infected cell, which corroborates the curves in Figure 34 and shows the location of the antigens being formed. From these results (Figs 35 and 36), it is seen that S antigen appears at 3 hours in the nucleus and spreads slowly to the cytoplasm However, the HA antigen appears at 4 hours and, from the beginning, is most prominent in the cytoplasm Even at 6 hours there is not much HA antigen found in the nucleus (Fig 36) Finally, the greatest concentration appears in the outer limiting membrane of the cell with the HA antigen at 14 hours

These studies are beautifully corroborated by electron photomicrographs of influenza virus infected cells (Morgan et al, 1956) Even by careful search no finished, mature,

fully coated particles are seen anywhere in the infected cell nucleus or cytoplasm Mature particles are seen only in the outermost layer of the cell (Fig 37), where they are found in abundance and appear in such form that one is tempted to say that they reach maturation almost at the moment of reaching the outer membrane

More evidence on this point can be seen from examining infected cells of the chorio-allantoic membrane in de-embryonated eggs Such cells, after beginning to discharge virus, continue to do so for many hours If at any time the cells are opened, noninfective hemagglutinin may be found inside which may be the precursor material for mature virus The life of the mature particle in the cell is short, probably only 30 minutes (Henle et al, 1956) The virus in the outer layer can be freed from the cell at any time by the action of RDE This suggests that the virus enzyme plays a role in extrusion

From the foregoing facts, the following picture emerges Virus which is properly adsorbed penetrates the cell, where it goes into a noninfective stage, the details of which are not known The first sign of virus multiplication then appears in the cell nucleus, where the RNA antigen is being synthesized This material then goes out into the cytoplasm where the HA antigen is being formed, and the final process of assembly is the covering of the S antigen with HA and lipid material This appears to occur just at the limiting membrane of the cell and extrusion of the particles takes place without gross or even microscopic evidence of damage to the cells, which continue to produce virus over long periods of time Other evidence consistent with this view is the action (LeClerc, 1956) of ribonuclease in preventing virus multiplication in cells at one stage, although they reach a refractory state late in production, indicating the appearance of complete particles Evidence of phenotypic mixing, the production of coats which come from two different parents, has been obtained with these viruses, and this is consistent with a picture of the separate production of S and HA antigens This evidence is reviewed with studies of multiple infection

Formation of Filaments Some strains of influenza virus, especially those that are examined shortly after isolation from human infections, contain large numbers of long filaments mixed with the usual spheres The filaments are about the width of virus particles (Fig 38) but often several hundred times as long They are made up, at least in part, of specific virus material Red cells stick to them at any point When the filaments are mechanically broken up, the HA titer of the suspension rises, but the infective titer does not These long, somewhat brittle rods contain perhaps one infectious particle The internal structure (Morgan et al, 1956) is not like that of influenza virus, and the rods are lysed by agents which are destructive to the host cell membrane but not to normal virus particles, suggesting that the filaments may include normal cell constituents (Burnet, 1956). There are similar filaments, which

FIG 38 Showing influenza filaments coming from the wall of an infected cell They are devoid of internal structure (Morgan, et al, 1956, Structure and development of viruses observed in the electron microscope III Influenza virus, J Exper Med 104, 171-182)

have no HA activity, extruded from normal cell membranes. It seems possible that there is some abnormal mechanism of virus extrusion at work, possibly in an area of the cell where no S substance is present, in which both host and virus elements get involved

Formation of Noninfectious Virus. It seems to be quite a common phenomenon among viruses that a fairly large proportion of the virus formed is inactive It is also likely that a number of different phenomena are responsible for this lack of activity Some of the various types of inactive influenza virus may be listed as follows:

1. Noninfective virus in normal yields In virus prepared under what may be considered as optimal conditions, a large proportion of the seemingly normal particles do not infect By comparing the infectivity of influenza virus for eggs, or its ability to form plaques or to form red cell dimers under proper conditions, with a particle count as determined by electron microscopy (virus particles absorbed to red cell ghosts), it is found that only about 10 per cent of the influenza hemagglutinating particles infect (Isaacs, 1957)

A. Part of this noninfective virus may actually be intact virus which fails to infect because it remains unadsorbed, perhaps due to lack of effective contact between virus and cells

B Part of the inactivity may be due to abortive adsorption. This involves adsorption to sites from which infection cannot proceed, or possibly adsorption to cells which are not competent to produce virus.

C The noninfective virus may be defective virus, and it may be defective because of faults in assembly of parts or some of the subunits may in themselves be defective Some of these possibilities will be considered under (2) and (3).

D. Another possibility is that the virus may have been thermally inactivated after formation. In the case of allantoic fluid virus, some of the earlier particles produced may rest in the allantoic sac at 37° for long periods of time and the half-life of a particle at this temperature is short (Horsfall, 1955).

2. Noninfectious virus from yields where the input multiplicity was very high When cells are inoculated with certain influenza strains under conditions where the infecting multiplicity is high (2 or more per cell), the yield in terms of hemagglutinin may be almost normal, but the number of infective particles (allantoic sac) may be markedly depressed (von Magnus, 1954). The number of infective particles per HA unit in "normal" virus is usually 10^6 or slightly more, while the yield after a large inoculum may have only 10^2 or less infective units per HA unit The effect is increased sometimes through several egg-to-egg passages with large inocula Some strains give this inactive virus more readily than others. When these yields of low infectivity are examined in the electron microscope, the number of particles may be nearly normal, but many particles appear flattened The particles are less dense than normal ones, possibly because they contain a higher proportion of lipid, and the amount of RNA per particle for influenza may be only 30 per cent of normal (Ada, 1957). There is some evidence that the so-called inactive particles do infect but give rise, in turn, to defective particles. If cells are multiply infected with inactive virus (UV) plus a single particle of normal virus, the yield will have a low infectivity/HA ratio It is possible that multiple infection of the cell induces a very disordered virus production process In interpreting these results, one must be cautious to eliminate other ancillary causes of inactivation, such as heat NDV does not produce this effect

3 Inactive virus from special hosts If influenza virus (ordinary strain) is inoculated into the brains of mice, a hemagglutinin is produced (Schlesinger, 1950), but infection is limited to a single cycle, and the "virus" produced is inactive It apparently agglutinates normally but does not infect; hence, the course in the brain is limited to a single cycle. Infection of HeLa cells produces a similar reaction (Henle et al., 1955) This is like the previous type of inactive virus except that it appears to be completely noninfective In the electron microscope the particle appears to be flattened Some host cells are incapable of producing perfect virus particles, for reasons unknown

Almost all animal viruses that have been investigated show a discrepancy, often a large one, between the total particle count and the count of infective particles With bacterial

viruses, the discrepancy is very small. It is tempting to speculate that the process of assembly from subunits is one which can take place more efficiently in the small compass of a bacterial cell than in the much larger volume occupied by most mammalian cells. Whatever advantages the animal virus gains by having subunits manufactured in different pools and then assembled is evidently done at some, or perhaps a large, sacrifice in efficiency so that many defective units are produced or subunits remain unused and wasted. It has been suggested that, since the assembly process is something more typically viral than the other synthetic processes going on in an infected cell, derangement of the assembly mechanism may be a fruitful point of attack for chemotherapy, for example (Luria 1958).

Genetics of Myxoviruses. Animal viruses appear to contain either DNA or RNA but probably not both. The myxoviruses are RNA viruses and therefore are of special interest because, thus far, the mechanics of inheritance by means of RNA are not known. Influenza contains about 1 per cent and FPV about 3 per cent RNA and, in each case, all of this appears to be located within the particle as part of the S antigen. With high input multiplicities of virus, the yield contains less RNA per particle (cf. incomplete virus, above). The base ratios in the RNA differ from strain to strain, and there is also some unconfirmed indication that the base ratios may change in the same virus, depending on the host species in which it grows (Ada, 1957). Electron photomicrographs of myxoviruses after preliminary treatment with trypsin and other reagents can be stained with phosphotungstic acid to show a many-stranded ring structure, which may possibly be RNA (Valentine and Isaacs, 1957a, b).

The present knowledge of myxovirus genetics may be summarized briefly by stating that it is in a very primitive state. This is due, at least in part, to the fact that only very crude methods of examination have been used. Most of the reported work has been done with influenza A. A number of naturally occurring strains of this organism differ from each other in terms of antigenic pattern, virulence, heat stability of hemagglutinin and other characters. When cells are infected, each with the two virus types, the yield from this infection may contain some particles in which the original characters from two different parents appear (recombinants). The best example (Burnet and Lind, 1951) consists of a cross between two different strains which differ by serotype (W and M) and in virulence for the mouse (intracerebrally) (V and A). From a mixed infection of W-V and M-A can be derived the parent types and also W-A, which is recombinant. Strain M-V occurs rarely. The W-A strains appear to be fairly stable and retain their new characters on passage. It is also possible to recover characters from heat or UV inactivated virus (Burnet and Lind, 1954; Gotlieb and Hirst, 1956). If strain W-V is inactivated by UV and inoculated into eggs with active M-A strain M-V can be recovered quite readily. Apparently, the active virus can rescue a character (virulence) from the inactive agent.

A number of other characters have been used in recombination tests, but they will not be reviewed here, since they do not as yet lead to any clear-cut interpretation of RNA genetics. What is presently lacking is quantitative data on frequency of recombination, on yields from single cells, on linkage and other parameters. There is no doubt that exchange of characters does occur with some viruses, but the mechanism of exchange is not clear. Similar preliminary findings have been reported with herpes and with psittacosis and vaccinia.

Phenotypic Mixing. In the section on bacterial viruses, the phenomenon of phenotypic mixing was discussed. Double infection of a bacterial cell with two phage strains resulted in the formation of a tail which was like type "A" (for example) in a virus which was genotypically "B" and vice versa. Tails were also found which contained mixed antigens "A" and "B." A formally analogous situation is found with influenza virus. If influenza strains, type A and B, are used to infect a single cell, it can be shown that as many as 85 per cent of the progeny of this infection will have both A and B antigens on the virus surface (Gotlieb and Hirst, 1954). Nevertheless, the virus particles are all either A or B genetically. This is another example of the result of separate production and assembly of virus subunits. When one realizes

have no HA activity, extruded from normal cell membranes. It seems possible that there is some abnormal mechanism of virus extrusion at work, possibly in an area of the cell where no S substance is present, in which both host and virus elements get involved

Formation of Noninfectious Virus. It seems to be quite a common phenomenon among viruses that a fairly large proportion of the virus formed is inactive It is also likely that a number of different phenomena are responsible for this lack of activity. Some of the various types of inactive influenza virus may be listed as follows.

1. *Noninfective virus in normal yields.* In virus prepared under what may be considered as optimal conditions, a large proportion of the seemingly normal particles do not infect. By comparing the infectivity of influenza virus for eggs, or its ability to form plaques or to form red cell dimers under proper conditions, with a particle count as determined by electron microscopy (virus particles absorbed to red cell ghosts), it is found that only about 10 per cent of the influenza hemagglutinating particles infect (Isaacs, 1957)

A. Part of this noninfective virus may actually be intact virus which fails to infect because it remains unadsorbed, perhaps due to lack of effective contact between virus and cells.

B. Part of the inactivity may be due to abortive adsorption This involves adsorption to sites from which infection cannot proceed, or possibly adsorption to cells which are not competent to produce virus

C. The noninfective virus may be defective virus, and it may be defective because of faults in assembly of parts or some of the subunits may in themselves be defective. Some of these possibilities will be considered under (2) and (3)

D. Another possibility is that the virus may have been thermally inactivated after formation. In the case of allantoic fluid virus, some of the earlier particles produced may rest in the allantoic sac at 37° for long periods of time and the half-life of a particle at this temperature is short (Horsfall, 1955).

2. *Noninfectious virus from yields where the input multiplicity was very high.* When cells are inoculated with certain influenza strains under conditions where the infecting multiplicity is high (2 or more per cell), the yield in terms of hemagglutinin may be almost normal, but the number of infective particles (allantoic sac) may be markedly depressed (von Magnus, 1954). The number of infective particles per HA unit in "normal" virus is usually 10^6 or slightly more, while the yield after a large inoculum may have only 10^2 or less infective units per HA unit. The effect is increased sometimes through several egg-to-egg passages with large inocula. Some strains give this inactive virus more readily than others. When these yields of low infectivity are examined in the electron microscope, the number of particles may be nearly normal, but many particles appear flattened The particles are less dense than normal ones, possibly because they contain a higher proportion of lipid, and the amount of RNA per particle for influenza may be only 50 per cent of normal (Ada, 1957). There is some evidence that the so-called inactive particles do infect but give rise, in turn, to defective particles If cells are multiply infected with inactive virus (UV) plus a single particle of normal virus, the yield will have a low infectivity/HA ratio It is possible that multiple infection of the cell induces a very disordered virus production process. In interpreting these results, one must be cautious to eliminate other ancillary causes of inactivation, such as heat. NDV does not produce this effect.

3. *Inactive virus from special hosts* If influenza virus (ordinary strain) is inoculated into the brains of mice, a hemagglutinin is produced (Schlesinger, 1950), but infection is limited to a single cycle, and the "virus" produced is inactive It apparently agglutinates normally but does not infect; hence, the course in the brain is limited to a single cycle Infection of HeLa cells produces a similar reaction (Henle et al, 1955). This is like the previous type of inactive virus except that it appears to be completely noninfective In the electron microscope the particle appears to be flattened Some host cells are incapable of producing perfect virus particles, for reasons unknown

Almost all animal viruses that have been investigated show a discrepancy, often a large one, between the total particle count and the count of infective particles. With bacterial

viruses, the discrepancy is very small. It is tempting to speculate that the process of assembly from subunits is one which can take place more efficiently in the small compass of a bacterial cell than in the much larger volume occupied by most mammalian cells. Whatever advantages the animal virus gains by having subunits manufactured in different pools and then assembled is evidently done at some, or perhaps a large, sacrifice in efficiency so that many defective units are produced or subunits remain unused and wasted. It has been suggested that, since the assembly process is something more typically viral than the other synthetic processes going on in an infected cell, derangement of the assembly mechanism may be a fruitful point of attack for chemotherapy; for example (Luria, 1958).

Genetics of Myxoviruses. Animal viruses appear to contain either DNA or RNA but probably not both. The myxoviruses are RNA viruses and therefore are of special interest because, thus far, the mechanics of inheritance by means of RNA are not known. Influenza contains about 1 per cent and FPV about 3 per cent RNA and, in each case, all of this appears to be located within the particle as part of the S antigen. With high input multiplicities of virus, the yield contains less RNA per particle (cf. incomplete virus, above). The base ratios in the RNA differ from strain to strain, and there is also some unconfirmed indication that the base ratios may change in the same virus, depending on the host species in which it grows (Ada, 1957). Electron photomicrographs of myxoviruses after preliminary treatment with trypsin and other reagents can be stained with phosphotungstic acid to show a many-stranded ring structure, which may possibly be RNA (Valentine and Isaacs, 1957a, b).

The present knowledge of myxovirus genetics may be summarized briefly by stating that it is in a very primitive state. This is due, at least in part, to the fact that only very crude methods of examination have been used. Most of the reported work has been done with influenza. A number of naturally occurring strains of this organism differ from each other in terms of antigenic pattern, virulence, heat stability of hemagglutinin and other characters. When cells are infected, each with the two virus types, the yield from this infection may contain some particles in which the original characters from two different parents appear (recombinants). Apparently, the active virus can rescue a character (virulence) from the inactive agent.

A number of other characters have been used in recombination tests, but they will not be reviewed here, since they do not as yet lead to any clear-cut interpretation of RNA genetics. What is presently lacking is quantitative data on frequency of recombination on yields from single cells, on linkage and other parameters. There is no doubt that exchange of characters does occur with some viruses, but the mechanism of exchange is not clear. Similar preliminary findings have been reported with herpes and with psittacosis and vaccinia.

Phenotypic Mixing. In the section on bacterial viruses, the phenomenon of phenotypic mixing was discussed. Double infection of a bacterial cell with two phage strains resulted in the formation of a tail which was like type "A" (for example) in a virus which was genotypically "B" and vice versa. Tails were also found which contained mixed antigens "A" and "B." A formally analogous situation is found with influenza virus. If influenza strains, type A and B, are used to infect a single cell, it can be shown that as many as 85 per cent of the progeny of this infection will have both A and B antigens on the virus surface (Gotlieb and Hirst, 1954). Nevertheless, the virus particles are all either A or B genetically. This is another example of the result of separate production and assembly of virus subunits. When one realizes

that the genetic material of the virus is produced in the nucleus and the type-specific material (hemagglutinin) is produced in the cytoplasm and probably applied to the core just before extrusion, it becomes clear why the outer and the inner parts of the virus do not coincide in terms of origin It also illustrates the fact that the coating pools of different viruses can get mixed in the cell and both will fit into the same virus coat The same situation is encountered with poliomyelitis virus types I and II (Sprunt et al, 1955, Ledinko, unpublished) where mixed infection of HeLa cells results in virus which can be neutralized by either type I or type II serum

The Behavior of Other Animal Viruses in Mammalian Cells. It will be useful to consider briefly a few other viruses in somewhat the same way that the myxoviruses have been covered

Polioviruses. This is an interesting group of viruses Until their ability to grow in many kinds of tissue culture was demonstrated, they could be handled in the laboratory in only the most restricted manner The virus is a small particle, about 30 mμ in diameter, round in shape and very stable in the extracellular form It can be extracted with ether without loss of titer, probably because it contains no lipid, only protein and RNA. RNA is present to the extent of 25 per cent When purified, the virus can be crystallized (Schwerdt and Schaffer, 1956) In intact animals, the strains freshly isolated from human beings will multiply satisfactorily only in primates, though some strains have been adapted to the intracerebral route in mice and to chick embryos. [illegible] stream In tissue culture preparations, it will infect a variety of cells of primates, such as kidney epithelium, muscle or embryonic and cancerous tissues It multiplies poorly in primate kidney cells in the intact animals (Kaplan, 1955)

Much of the recent investigation of the virus has been carried out in tissue culture, either of monkey kidney or of HeLa cells Adsorption of the virus to these cells is fairly rapid and complete and requires calcium (Bachtold et al., 1957). Nothing is known about sites of adsorption on the cells or about penetration. Once inside the cell, multiplication is rapid, and virus is excreted after 3 to 6 hours, depending on the host cell and conditions of cultivation Cells that begin to excrete virus usually die within a short period of time (Lwoff et al, 1955), disgorging the cell contents Each cell may produce as many as 20,000 particles but, for a virus the size of poliomyelitis, this constitutes less than 2 per cent of the total cell mass The relatively small proportion of total cell metabolism which is due to virus synthesis is also reflected in the fact that HeLa cells can synthesize virus very well when they are in a nutrient medium consisting of (Eagle and Habel, 1956) electrolyte and glutamine. Since this is insufficient for the nutrition of the cell alone, the virus is being synthesized out of cell reserves

When poliomyelitis virus is adsorbed to cell monolayers overlaid with nutrient agar, cell lysis also occurs, and the plaques (compared with NDV or influenza) are large and grow rapidly, since the virus is small and diffuses rapidly Only 3 to 4 per cent at most of the particles in a suspension (from monkey kidney cells) form plaques Again, the reasons are not clear, but the occurrence of imperfect particles is one possibility. By means of differential centrifugation, the virus population has been separated into two fractions (Le Bouvier et al, 1957). One fraction is infectious, contains 25 per cent RNA and gives a distinct band in an agar diffusion test against immune sera The other fraction is not infectious, contains protein but little RNA, and gives a different band in the immunologic test It is not possible to say without further evidence whether the second fraction is a virus precursor which had not yet been incorporated into finished particles or whether it was defectively assembled virus in which RNA was omitted or in which the antigens were defective

There are 3 serologic types of poliomyelitis virus, unrelated by neutralization tests However, if cells are infected with both type I and type II virus, the yield will contain a majority of particles which can be neutralized by both type I and type II antisera. Such particles contain a mixture of I and II antigens, and since, genotypically, the particles seem to be either I or II (Ledinko, unpub-

lished), a separate formation of genetic and coat material seems to be very likely

This point of view is also supported by experiments in which poliomyelitis particles are damaged by high concentrations of phenol. This treatment renders the RNA in the particle accessible to RNAase action, yet the particles are still able to infect, albeit with a low efficiency (Colter et al, 1957) These experiments suggest, as do the similar ones with tobacco mosaic virus, that the essential material for carrying the information necessary for virus synthesis does not reside in the protein coat but rather in other elements, such as RNA

A number of mutants of poliomyelitis virus have been described, especially since the development of the plaque technic Some of these, such as a strain adapted to growth in the chick embryo are doubtless multistage mutants isolated by a prolonged selective process Mutants arise spontaneously and maintain their character on subpassage Mutations involving changes in plaque type, heat stability, resistance to normal serum inhibition, neurotropism and a host of other characters, have been described Where the back-mutation rate has been measured, it was found to be of a similar order of magnitude as that found with DNA viruses The behavior of mutants suggests that the virus is haploid, and there are no obvious special peculiarities of RNA mutants Recombination with poliomyelitis has not yet been accomplished

Vaccinia Virus. In many ways this virus is very different from poliomyelitis It is very large, about 200-300 mμ in diameter It is very complex chemically, containing proteins, lipids, carbohydrate and DNA At least three separate soluble fractions have been described (L, S and HA) which can be separated from the virus particle without loss of viability By electron microscopy it is also complex, with a double outer membrane and a complicated center like a nucleus (Fig 39) (Morgan et al, 1954) While mainly dermatropic in its natural host, it has been adapted to a variety of animal hosts and grows well in tissue culture Its attachment mechanism to cells is not understood, and the virus is neutralized poorly with immune sera When this virus enters a cell, there is a loss of infective titer, though with some hosts this is slight The site of virus synthesis is not known and, by electron microscopy, the particles appear at first in a homogeneous matrix which is just outside the cell nucleus This matrix contains a lot of DNA, and the particles appear in this area by what may be stepwise maturation (Gaylord and Melnick, 1953) When first visible as particles in the cell, they are surrounded by a single membrane After extrusion from the cell, the outer membrane is double (Morgan et al, 1954) The areas of virus concentration are described in classic pathology as inclusions

FIG 39 Two particles of vaccinia virus—one shows the double outer membrane very well, and the other shows the light nucleuslike body and the internal structure (Morgan, et al, 1954, Structure and development of viruses observed in the electron microscope II Vaccinia and fowl pox viruses J Exper Med *100*, 301-310)

Vaccinia virus grows on the chorio-allantoic membrane of eggs, where it forms lesions which are necrotic but also show some proliferation In this and other respects, they are distantly related to tumor-inciting agents, such as the virus of rabbit fibroma The virus also forms proliferative lesions in tissue culture Laboratory strains differ from each other in a number of characters, and with mixed infection of single cells recombinations of characters occur which are stable on passage (Fenner, 1958)

Tests for the infectivity of vaccinia preparations show that a variable proportion of the population will not, or at least does not, infect. The reasons for this are not clear.

Adenoviruses The viruses of this group have been discovered recently, and they are difficult to handle, even with tissue culture methods This is an example of a small DNA virus Its size is 60 mμ Little is known about its mode of adsorption to the cell, but multiplication appears to occur solely in the nucleus The virus appears in the nucleus in large crystalline arrays which give a positive *Feulgen test for DNA (Bloch et al., 1957)* With time, the crystals break up, and the viruses become dispersed in the cytoplasm Inclusions of a crystalline protein are found in the virus crystals (Morgan et al, 1957).

Very few of the statements made in the previous section about myxoviruses can be used as a basis for generalities about animal viruses because of lack of direct information In respect to virus composition, there are at least two major divisions: viruses that contain no lipid and those that do, and those which contain RNA or DNA The viruses which contain no lipid are, in general, small and are resistant to the action of ether. Members of this group include poliomyelitis, Coxsackie viruses, adenoviruses, etc (Andrewes and Horstman, 1949) All animal viruses appear to contain either RNA or DNA None is known to contain both The myxo agents and poliomyelitis are examples of RNA; adenoviruses, vaccinia and probably herpes are examples of DNA viruses

Very little can be said about receptors or attachment mechanisms of any viruses except the myxo group After penetration, an eclipse period is found for nearly every virus that has been tested adequately, including Rous sarcoma virus (Prince, 1958) Growth curves usually show that something of the order of 90 per cent or more of the absorbed virus disappears. In no case is the disappearance complete, and the beginning of new synthesis is taken as the time when there is an increase in infective titer. The eclipse or latent phase varies from a few hours to 10 or more hours, depending largely on the virus, conditions of growth, etc. The mode of release is frequently obscured by rapid re-adsorption.

Evidence for the production of several virus constituents in separate sites of the cell is lacking for most viruses. The early appearance of S substance from myxoviruses in the nucleus has been mentioned. Herpes virus antigen also appears first in the nucleus and later in the cytoplasm (Lebrun, 1956) Adenoviruses appear in the nucleus also For the other viruses, the synthesis of particles from separately produced constituents in the cell is not established and it is still possible that the eclipse phase for psittacosis, for example, may be a case of masking rather than dissolution

Changes in the Host Cell. *No animal* virus has been found which has an intrinsic metabolism of its own, and it is generally assumed that virus synthesis inside the host cell is accomplished with energy mobilized by the enzyme systems of the host Inhibitors of energy production such as cyanide, or an uncoupler of phosphorylation like 2-4 dinitrophenol, are generally able to block virus synthesis (Eaton, 1952) This is taken to mean that virus synthesis is dependent on the Kreb's cycle enzymes, for example. This approach to control of virus multiplication is elaborated in Chapter 6.

The morphologic changes in infected cells are also quite varied, and they have long been the object of intensive study by pathologists Unfortunately, much of the pathology which occurs is not very specific in terms of the processes which are going on Disintegration of the nucleus, disintegration of the cell mem-

croscopy, it has not been feasible to reconstruct a logical series of events leading up to the demise of the cell. Inclusion bodies are

the only fairly certain morphologic sign of virus infection

Inclusion bodies are areas staining characteristically within cells which are the result of infection. The inclusions may be either in the cytoplasm or the nucleus. They may be made up of virus particles, or they may be scars of former infection, and the latter case is usually true of intranuclear inclusions. Intranuclear inclusions have been classified as type A or B by Cowdry, on the basis of severity, the latter being milder.

The inclusions which have received the most detailed descriptions are those of the larger viruses, like psittacosis or vaccinia. Intracytoplasmic inclusions are found in a number of human virus infections such as psittacosis, variola, rabies and the encephalitides. In the case of psittacosis (Bedson and Bland, 1932), it was found that a large amorphous mass first appeared in the cell cytoplasm. After some time, formed elements appeared in it and developed in a succession of forms not unlike that of malarial parasites. Micromanipulation and micropipetting of psittacosis and fowlpox inclusions have demonstrated that they contain the infective agent. In fact, such inclusions probably are made up largely of virus particles and, in some instances, they appear to be surrounded by a membrane.

Intranuclear inclusions have been studied in less detail than the cytoplasmic ones. In some infections such as herpes simplex, the infection leaves a nuclear scar which has been shown by fluorescent antibody (Lebrun, 1956) to be nonspecific, i.e., to contain no virus antigen. It is relatively easy to stimulate the formation of intranuclear inclusions by rather general types of cell injury, not involving viruses. On the other hand, certain infections such as those with adenoviruses produce intranuclear inclusions which are virus crystals. Infections in which intranuclear inclusions occur include herpes zoster, herpes simplex, varicella and pseudorabies of swine. B type inclusions occur in yellow fever and in Rift Valley fever. Occasionally the presence of inclusion bodies is used as evidence for virus infection. Rabies is a good example of the use of inclusions diagnostically.

Multiplication of Plant Viruses

Viruses are perhaps the most common type of agent causing disease in plants. Plant viruses are known only among angiosperms or flowering plants, but perhaps this is only because they have been studied the most thoroughly. The best-studied examples are the infections of economically important plants.

Viruses may be introduced into plants in a variety of ways: by insects, wind, soil, contact and grafting. Dodder, which is a plant parasite, can be used to transfer infection from one plant to another by having it parasitize two plants at once. Once a plant is infected, the infection may be carried on through vegetative propagation of the plant (as in potatoes), or the virus may pass to other generations through the seed or rarely through pollen.

The virus usually spreads rapidly after infection through the whole plant via extracellular fluid. An exception occurs when the site of infection becomes necrotic so rapidly that further extension of the infection stops, trapping the virus. This is called "hypersensitiveness." Sometimes plants that are infected recover in the sense that late-appearing shoots look normal although they contain virus. The reason for this tolerance is not clear. The local necrosis reaction of hypersensitivity furnishes the basis for a pock method of counting infectious particles. Infection of a plant with one virus which in itself may be asymptomatic may produce immunity (interference) against another lethal strain.

Plant viruses offer extremely favorable conditions for some types of study and very great difficulty for others. As in the other virus groups, the principal attention of investigators has been focused on a single virus, tobacco mosaic virus (TMV). There are a number of hosts for this virus but, in actual practice, tobacco plants are usually used either in entirety or as detached leaves.

The virus is a rod which is about 300 mμ long on the average and 15 mμ wide, and consists of an inner helix of RNA and an outer coat of protein. The virus is titrated by rubbing on *N. glutinosa* leaves. Wherever hair cells are properly injured by this treatment, a virus particle may enter a cell and start an infection. Because of hypersensitivity, the infection becomes localized, and each site can be counted as a plaque. Because of a number of variables, it is extremely difficult to get reproducible counts by this method, and usually determinations are made in terms of comparing two preparations, inoculated on oppo-

site halves of the same leaves. In addition, the efficiency of infection is very low, and it may require as many as 10^6 particles of virus to initiate a single necrotic lesion This difficulty in infecting cells with small amounts of virus and the absence of any specific mechanism for attachment of viruses to host cells is characteristic of plant viruses The use of such large amounts of virus on the leaf for infection precludes any very decisive study of early infection in the leaf. There is no method of infecting and studying single cells To counteract these disadvantages is the relatively simple structure of plant viruses, and the possibility of getting very large amounts of highly purified material, since the virus can be crystallized readily TMV makes up 10 per cent or more of the dry weight of the plant, and a single cell may yield 60 million particles

The simple structure of the virus has been mentioned already It is a long protein tube, and the RNA is buried within it The virus contains 5 6 per cent RNA, which is not accessible to RNAase in the native virus form. Crystallographically, the virus is made up of small (27 mμ) units of length which are repeated throughout the entire length In a preparation from a plant, the particles are of a wide variety of lengths, although this may be due to manipulation, and there is much evidence that 300 mμ is the native size and the infective size.

This brings up the problem, as with other viruses, of the noninfective particles, and again the answer is not clear It may take 10^5 to 10^6 particles to produce a plaque The methods of inoculation are crude, and a great deal of wastage cannot be eliminated The occurrence of precursors or incomplete virus will be taken up later It is also possible that much virus may be inactivated by breaking the rods at less than the optimal length

TMV is made up of RNA (5 6%) and protein The two may be readily separated from each other. Under proper conditions, the virus protein has a tendency to reaggregate in the form of rods—rods which are of quite variable length and do not contain any RNA (Schramm, 1947). When protein and RNA are mixed under similar conditions, the RNA forms a core around which a protein coat assembles. This appears very much like the original particles, and these reformed particles are infective, sometimes to 30 per cent of the original value (Fraenkel-Conrat, 1957). If the RNA from one virus is coated with the protein from another virus, the resulting agent will give rise to virus which corresponds to the RNA present and not to the protein RNA carries the genetic specificity (Fraenkel-Conrat, 1956, Fraenkel-Conrat and Williams, 1955).

Finally, RNA itself is infectious (Gierer and Schramm, 1956), again with an efficiency of about 1 per cent of the virus from which it came In this form, the virus was not very stable. It was easily damaged by heat, and the RNA was accessible to RNAase which destroys it.

In view of these results on the primacy of RNA in infection, it is not surprising that it is possible to bring about extensive changes in the protein coat of virus particles (blocking amino groups with iodine for example) without seriously altering the ability of the virus to infect (Stanley, 1943) The most likely role for the protein coat is that of a protector for the RNA.

The course of virus multiplication in infected plants has been studied extensively, but technical difficulties are great It is not known, for example, whether there is an eclipse period after virus infection, because there is such a tremendous excess of virus left on the leaf after inoculation There is also the difficulty that one must measure the average reaction of a great number of cells If the leaves are infiltrated with RNAase just before or just after infection with TMV, infection is completely inhibited, suggesting an early change in the virus after inoculation (Hamers-Casterman and Jeener, 1957) By 2 hours, the virus is RNAase-resistant On the other hand, if infected leaves are irradiated with ultraviolet light and the effect on the number of infective centers is determined, it will be found that the sensitivity of virus after entry into the leaf is the same as that of free virus (Siegel and Wildman, 1956) This condition lasts for about 2 hours after infection, after which the infective centers become progressively more resistant to inactivation and, after 5 hours, the inactivation curve becomes multiple hit. These changes are not easy to interpret but suggest that the virus

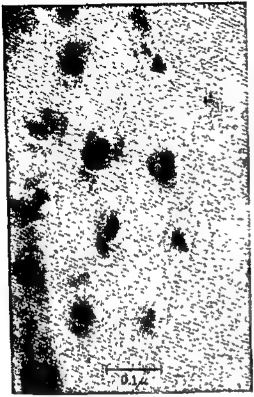

FIG 40 Portion of polyhedron of *B mori*, showing single viral particles included in the crystalline matrix (Morgan, C, Bergold, G H, Moore, D H, and Rose, H M, 1955, The macromolecular paracrystalline lattice of insect viral polyhedral bodies demonstrated in ultrathin sections examined in the electron microscope, J Biophys & Biochem Cytol *1*, 187-190)

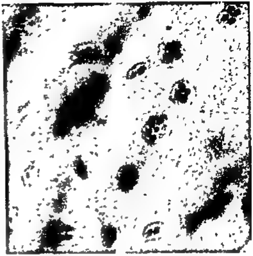

FIG 41 Portion of polyhedron of *P dispar*, showing characteristic bundles of rod-shaped viral particles inclosed by limiting membrane (Morgan, C, Bergold, G H, Moore, D H, and Rose, H. M, 1955, The macromolecular paracrystalline lattice of insect viral polyhedral bodies demonstrated in ultrathin sections examined in the electron microscope, J Biophys & Biochem Cytol *1*, 187-190)

goes through definite stages in which it is sheltered to different degrees from a UV effect

As with other viruses, the substance of TMV seems to be synthesized in the plant from small molecular weight materials assimilated by the plant after infection (Meneghini and Delwiche, 1951) Once made, the particles are stable with little or no turnover However, excess RNA accumulates in infected plants beyond what can be found in the virus (Basler and Commoner, 1956) Also, there are several RNA-free proteins found in the tissues of infected plants, and these consist largely of virus protein in various states of aggregation Some of this virus protein in the plant may be virus precursor protein, but some may have become aggregated without RNA to form noninfectious products The RNA itself is not highly regular in composition, as reflected in a variable base ratio for viruses grown under various conditions (Commoner and Basler, 1956)

Mutations in plant viruses are not uncommon, and there are numerous examples which seem to be stable mutants Recombination experiments at present are inconclusive The feeding of thiouracil to infected plants results in a large incorporation into TMV nucleic acid as a replacement of uracil (Jeener, 1956) Such virus has diminished infectivity

Persistent infection of plants without symptoms is a common event with plant viruses, and this is dealt with under the section on latency

VIRUS DISEASES OF INSECTS

Virus infections of insects can be grouped in 4 classes (1) agents that cause disease

and are lethal for insects, (2) agents that are pathogenic for vertebrates but also multiply in insects (or acaridae), (3) agents that cause diseases of plants but also multiply in insects and (4) an agent which produces CO_2 sensitivity in Drosophila. In the first 3 groups especially it is very difficult to perform adequate quantitative titrations of the viruses, and as a result knowledge of these agents is very restricted and it is summarized briefly.

Agents Causing Disease Exclusively in Insects. The viruses multiply extensively during the larval stage and, in the case of the Crane fly (Williams and Smith, 1957), come to make up 25 per cent of the weight of the larvae Many larval infections are accompanied by the production of large crystalline bodies which are made up of nonviral, nonlarval protein. Sometimes these are in the form of large polyhedra, sometimes small amorphous-shaped capsules Both forms are really protein crystals. The virus particles themselves are frequently caught up in these crystalline masses (Figs 40 and 41) where, by electron microscopy, they appear to be in a wide array of developmental stages (Bergold, 1953) In other diseases, the viruses are surrounded by a large, alkali-soluble capsule and are often surrounded by a membrane The virus particles contain DNA as the principal and probably sole nucleic acid The virus from the sawfly crystallizes readily

One further feature of these viruses which requires comment is the occurrence of latent infections In order to explain the sudden outbreaks of the disease in laboratory colonies, it is necessary to postulate that latent infection occurs over many generations in insects. Because of this and other features, these viruses are of great general interest, but the lack of a really good titration system is, at present, a serious handicap in studying them.

Agents Infecting Plants or Warm-Blooded Animals as Well as Insects. A number of viruses are known which attack man (cf. Arbor viruses, Chap 12) and are also capable of multiplying in arthropods, usually in mosquitoes among the insects and in ticks or mites among the acaridae. Very little quantitative work has been done with the infection in these arthropods, but it is known, for example, that yellow fever virus multiplies in the salivary gland and the stomach of *Aëdes egypti* mosquitoes, and there is some evidence for the transoverian transmission of other viruses in ticks. In fact, wild caught mosquitoes have been a good source of "orphan viruses," some of which have been shown later to cause infection in man (West Nile virus) or in arthropods

Several plant viruses (Black, 1953) have now been shown to multiply in certain diptera, and this has been demonstrated unequivocally by insect-to-insect passage in the laboratory It is possible that multiplication in insects in nature is a common event, especially where a sucking insect is the natural vector for the virus It has not been technically possible to carry out quantitative studies

The Virus of CO_2 Sensitivity in Drosophila. The fourth variety of insect virus is a lone example (l'Heritier, 1958). This virus multiplies in injected flies and can be transmitted by a female fly to all offspring. The infection in itself is not lethal but renders the flies susceptible to CO_2 narcosis. Its mode of transmission from one generation to another is complex and comparable in mechanism with the transmission of prophage in bacteria.

So far, virus infections have not been found in other invertebrates except for the incrimination of the lungworm as the intermediate host for swine influenza (Shope, 1943), and this has been demonstrated only indirectly. Similarly, no known virus infections of Protozoans have been described The killing agent (kappa) found in paramoecia (Sonneborn, 1949) is structurally similar to rickettsiae

LATENT OR PERSISTENT VIRUS INFECTIONS

A virus which is so virulent that it invariably kills its host creates a condition of increasing difficulty for its own survival When a highly virulent myxoma virus was introduced into the wild rabbit populations of Australia (Fenner, 1957), the first waves of the ensuing epizootic were devastating However, the virulent strain tended to die with its victims, and less virulent derivatives began to appear, which were a major factor in subsequent waves. By a further extension of this adaptive process, variants may well appear which cause less and less inconvenience to the

host and, finally, some which cause none at all Such infections are called latent, and they are frequently persistent and form the main reservoir of viruses in nature. A true understanding of latency can be obtained only by studying infection at a cellular level, and this has been successful so far only with bacterial viruses.

Latency with Bacterial Viruses Bacteriophage latency is of two varieties, called (1) persistent infection and (2) lysogeny

PERSISTENT INFECTION A contaminating virus may persist in a continuously growing culture of bacteria over long periods of time if the bulk of the bacteria are resistant to virus infection and if susceptible mutants are thrown off occasionally (Benzer et al., 1950) The virus may persist at a low level in this culture by multiplying in these rare susceptible bacteria. This type of persistent infection is characterized by the fact that the virus can be removed readily and permanently by growing the bacteria in the presence of an antiviral serum The serum prevents the re-infection of new cells and shows that the propagation of mature virus is necessary for maintaining the infected state of the culture

LYSOGENY is a condition in which the ability of a bacterium to produce bacteriophage is hereditary The condition may be induced in a bacterium by infection with a temperate phage.

There are two principal types of bacteriophages: virulent and temperate (Lwoff, 1953) Virulent phage kills the bacterium, multiplies within it and finally lyses the cell Temperate bacteriophage may enter a host cell and pursue either of two courses In one case, the virus behaves like a virulent bacteriophage in all respects, in the other case, there is a series of events leading to the condition of lysogeny. The cell is not killed but survives and divides Some of the early progeny are lysogenic, and some are not Eventually, the lysogenic bacteria give rise to stable lysogenic clones in which each bacterium is lysogenic Lysogenic bacteria give rise to progeny which are normal in appearance and are in turn lysogenic However, a small proportion will give rise to viruses of the original infecting type This proportion may be small (10^{-6}) and depends on a number of factors, such as the kind of virus and the condition of the culture. Certain physical and chemical agents, called inducers (Lwoff, 1953), have the capacity to initiate phage production and lysis in all lysogenic cells, but a lysogenic bacterium cannot be lysed by either the original or closely related phages

The nonviral form of the temperate phage as carried in the bacterium is called prophage, and this may consist largely of the DNA of the infecting organism, which replicates without forming mature phage particles. In a bacterium which is about to become lysogenic, the infecting DNA does not replicate as usual but probably enters into some sort of close association with the bacterial chromosome, where it replicates at the same rate as purely bacterial regions of host DNA The region in which the prophage is located can be determined on the bacterial chromosome map (Lederberg and Lederberg, 1953), and there is evidence of homologies between bacterial and viral DNA in this region This region of the chromosome may be introduced into other bacteria by the process of recombination or by transduction The presence of prophage does not appear to harm the bacterial economy The use of inducers, such as ultraviolet light, may upset this harmonious accord, causing the prophage to go into a state of vegetative reproduction with the formation of mature particles However, prophage may mutate occasionally so that, on induction, no virus particles appear or they may be defective and lack the property of infectivity (Jacob and Wollman, 1956). Sometimes a prophage controls the production of certain bacterial antigens or other specific products such as toxin production by diphtheria (Groman, 1955) Even defective phages may control antigen production, in which case the role of the virus in the bacterial economy might pass unsuspected, detectable only because the bacterium is immune to re-infection with the same virus

Lysogeny is a state of parasitism at the genetic level There may be multiple lysogenic viruses in a single bacterium, and the main reservoir of bacterial viruses in nature consists of agents occurring in the lysogenic state.

Latent Infection of Animals Latent and persistent infections are common in animals The complex character of the host provides a multiplicity of ways in which the in-

fection may persist and, at the same time, makes it enormously difficult to discover the basis of the latency It is possible that some special virus form analogous to provirus may exist, or the viral agent may undergo loss of destructive properties, or the virus may be held in an extracellular or intracellular location where it is stable, or the rate of virus multiplication and cell destruction may be greatly slowed down so that cellular replacement can keep up with it Possibly all these mechanisms play a role in one or another latent infection, but it is difficult or impossible to understand the mechanism without single cell studies, the development of which is just beginning

In the following examples, a number of latent or modified infections are described briefly, which may give an idea of the breadth of problems involved in animals

Influenza The mechanism of persistence of influenza virus between human epidemics is unknown, and conceivably strains may be kept going in man by means of subclinical or sporadic infections The outbreaks of the very similar virus in swine occur in such a manner that Shope (1943) does not believe that the epizootic picture can be explained entirely by animal-to-animal transmission. Shope has suggested an additional cycle in which lungworm parasites of swine become infected, give off infected ova which are ingested by earthworms, which in turn are eaten by swine, after which the latently infected lungworms establish themselves in the lung The latent infection can be changed to an overt one by administering various kinds of shock treatment to the pig According to Shope, the influenza virus is latent in both the lungworm and the earthworm, and it cannot be demonstrated directly in either by the most delicate technic. Since the reversion from latency can occur only in the intact swine, the nature of the latent condition has not been clarified.

Herpes Simplex. The primary host for this virus is man Infection usually takes place early in life, sometimes with an extensive stomatitis This is usually, possibly always, followed by a latent infection which can persist throughout life, being activated by various physiologic states (such as menstruation) or affected by the occurrence of bacterial infections in the host. The recurrent form of the disease consists of vesicular lesions, frequently of the lip, and there is some suggestion that the recurrent vesicles always occur in the same area Very likely the dermal cells of the lip are latently infected There is no laboratory model of this infection, and the study of the herpes virus in single cells is just beginning.

Lymphocytic Choriomeningitis. This virus induces a chronic asymptomatic infection in mice The infection may spread in a mouse colony by the intra-uterine route There is doubtless some mortality from infection, even when it occurs early, but once the chronic condition is established superinfection is not fatal (Traub, 1939). These mice do not make neutralizing antibodies against the virus, suggesting that the early infection induced some form of immune tolerance.

Psittacosis. This infection, somewhat like LCM, occurs in nestling psittacine birds, and some of them die The survivors become healthy and, while they show no symptoms, often virus may be found in the spleen where it may be multiplying slowly. Physiologic and environmental effects are able to upset this balance, and crowding, for example, will cause some birds to become ill and excrete virus The chronic state does not confer any immunity (cf Chap 33)

Coxsackie and Echo Virus Infections In a search for agents in stools, it was found unexpectedly (Dalldorf and Sickles, 1948) that the intestine often contained a great many viruses which were pathogenic for the suckling mouse. Some of these viruses are the causative agents of specific disease syndromes, such as epidemic pleurodynia, but many of them are apparently harmless agents which multiply in the intestine without causing symptoms. There is little evidence that such infections are prolonged

A somewhat different situation is found with mouse poliomyelitis virus in mouse colonies where it is found that infection with one of several viruses of this group takes place early in life by contamination from the parents and, thereafter, the virus multiplies in the intestinal tract for long periods, without producing symptoms, except in that occasional mouse where the virus breaks through

in the central nervous system where it may cause a fatal infection (Olitsky, 1940)

Tumor Viruses. This class of agent furnishes the best examples of what may properly be termed true latency The infectious agent may come through the egg, through maternal milk or in other ways The virus grows in certain cells for long periods without giving any evidence of its presence There is some evidence (see later section on tumors) suggesting that there is a relationship of the virus with cellular genetic material like that which occurs with lysogeny Information about tumor viruses is too incomplete to furnish many interesting details at this time One example of latency often cited is that of Shope Papilloma virus in domestic rabbits, in which tumors can be incited by virus but where no detectable virus growth is found This may merely be a quantitative difference in the amount of virus produced (Beard 1956)

Other examples of latency could be cited, but they would add little to the picture given by the foregoing diseases In clinical medicine, latency is used in an even broader sense, including conditions which occur in the course of normal infection Almost all the virus diseases of childhood, for example, have a long silent (latent) period of incubation between the initial infection and the onset of the main manifestations of the disease There are at least two factors in this In almost all cases, the virus may first multiply in a location such as the pharynx where no symptoms (at least not classic symptoms) arise This may be followed by a spread through the blood stream of virus to other cells Here again as is often witnessed in laboratory examples, there is another delay between the peak of virus multiplication and the occurrence of cellular pathology The term "latency" is sometimes extended to cover examples of asymptomatic infection In influenza epidemics, for example, a large proportion of those infected have no symptoms, even though virus multiplies in their respiratory tract, and an antibody response ensues Such silent infections occur with many viruses, and the cause is obscure The infections are not necessarily persistent.

There is another large group of viruses which are latent in tissues and are found only by manipulation of these tissues, either by serial animal-to-animal passage or through cell culture It has been common experience for years that, when an organ was ground and passed serially, very often a pathogenic virus would appear which was frequently lethal Examples are virus III, in rabbit testis (Rivers and Tillett, 1924), and pneumonia virus of mice (Horsfall and Hahn, 1940). However, the extraordinary number of such viruses was not appreciated until cell culture was undertaken on a large scale

The culture of epithelial cells of monkey kidney, for example, has been carried on on a very large scale as a means of producing poliomyelitis vaccine Incidental to this and other work with monkey kidneys, a number of viruses have been found which appeared spontaneously in kidney cell culture (Hull et al , 1956) and brought about lysis of the cells Most of these agents, once they appeared, were readily propagated in series, but few have been linked definitely with any normally occurring infection The meaning of these findings is therefore not clear.

Somewhat similar results were obtained with test tube culture of the epithelium of surgically excised tonsils (Rowe et al , 1953) From such material, both fibroblasts and epithelium may grow and often, after even 6 or 8 weeks, the cells begin to die suddenly, and it can be shown that this is due to a virus which is readily propagated on HeLa or other cells Viruses are found in a large proportion of tonsils and they fall into a homogeneous group which has been subdivided on the basis of antigenic types into a number of subgroups (cf Chap 30) Some, such as type 3, are known to cause an epidemic type of respiratory infection, but others are associated with no recognized disease

No studies have been carried out as yet to determine the nature or the frequency of occurrence of this latency in the individual cells of a tonsil, but it appears to be a rare event.

The study of latency at a cellular level, in tissue culture, is just beginning, and it is too soon to draw conclusions from the studies which have already been carried out Ackermann and Kurtz (1955) showed that, if a culture of HeLa cells is heavily infected with poliomyelitis, most of the cells die, but a few survivors may grow out, and they may be maintained as infected cells in the presence of virus if sufficient virus antibody is included

fection may persist and, at the same time, makes it enormously difficult to discover the basis of the latency It is possible that some special virus form analogous to provirus may exist, or the viral agent may undergo loss of destructive properties, or the virus may be held in an extracellular or intracellular location where it is stable, or the rate of virus multiplication and cell destruction may be greatly slowed down so that cellular replacement can keep up with it Possibly all these mechanisms play a role in one or another latent infection, but it is difficult or impossible to understand the mechanism without single cell studies, the development of which is just beginning

In the following examples, a number of latent or modified infections are described briefly, which may give an idea of the breadth of problems involved in animals

Influenza. The mechanism of persistence of influenza virus between human epidemics is unknown, and conceivably strains may be kept going in man by means of subclinical or sporadic infections. The outbreaks of the very similar virus in swine occur in such a manner that Shope (1943) does not believe that the epizootic picture can be explained entirely by animal-to-animal transmission Shope has suggested an additional cycle in which lungworm parasites of swine become infected, give off infected ova which are ingested by earthworms, which in turn are eaten by swine, after which the latently infected lungworms establish themselves in the lung The latent infection can be changed to an overt one by administering various kinds of shock treatment to the pig According to Shope, the influenza virus is latent in both the lungworm and the earthworm, and it cannot be demonstrated directly in either by the most delicate technic. Since the reversion from latency can occur only in the intact swine, the nature of the latent condition has not been clarified.

Herpes Simplex. The primary host for this virus is man Infection usually takes place early in life, sometimes with an extensive stomatitis This is usually, possibly always, followed by a latent infection which can persist throughout life, being activated by various physiologic states (such as menstruation) or affected by the occurrence of bacterial infections in the host. The recurrent form of the disease consists of vesicular lesions, frequently of the lip, and there is some suggestion that the recurrent vesicles always occur in the same area Very likely the dermal cells of the lip are latently infected There is no laboratory model of this infection and the study of the herpes virus in single cells is just begininng.

Lymphocytic Choriomeningitis. This virus induces a chronic asymptomatic infection in mice. The infection may spread in a mouse colony by the intra-uterine route. There is doubtless some mortality from infection, even when it occurs early, but once the chronic condition ▪ established superinfection is not fatal (Traub, 1939) These mice do not make neutralizing antibodies against the virus, suggesting that the early infection induced some form of immune tolerance.

Psittacosis. This infection, somewhat like LCM, occurs in nestling psittacine birds, and some of them die The survivors become healthy and, while they show no symptoms, often virus may be found in the spleen where it may be multiplying slowly. Physiologic and environmental effects are able to upset this balance, and crowding, for example, will cause some birds to become ill and excrete virus The chronic state does not confer any immunity (cf Chap 33)

Coxsackie and Echo Virus Infections. In a search for agents in stools, it was found unexpectedly (Dalldorf and Sickles, 1948) that the intestine often contained a great many viruses which were pathogenic for the suckling mouse. Some of these viruses are the causative agents of specific disease syndromes, such as epidemic pleurodynia, but many of them are apparently harmless agents which multiply in the intestine without causing symptoms There is little evidence that such infections are prolonged

A somewhat different situation is found with mouse poliomyelitis virus in mouse colonies where it is found that infection with one of several viruses of this group takes place early in life by contamination from the parents and, thereafter, the virus multiplies in the intestinal tract for long periods, without producing symptoms, except in that occasional mouse where the virus breaks through

they can change host cell character must include the induction of unrestrained growth

The most convincing evidence in favor of the virus etiology of tumors is the growing list of neoplasms in which a viral agent is clearly implicated. This now includes classic types of tumors, such as mammary carcinoma and lymphatic leukemia (of mice) The status of the known examples of virus-induced tumor will be reviewed briefly

Virus-Induced Tumors of Birds. The domestic fowl is a bird with a very high incidence of spontaneous mesodermal tumors, many of which are virus-induced and include fibromas, sarcomas, myxomas, osteomas, lymphoid tumors and leukemias The causative agents are as varied as the tumors, each inducing growths of the sort from which it was procured The pioneer work in the field was done by Rous (1911) who demonstrated the tumor-inducing capacity of tumor filtrates from several different tumors This touched off a lively controversy as to the relevance of the virus to tumor growth and, in subsequent work, much attention was given to one of these agents, called Rous sarcoma virus, or RSV

Rous sarcoma virus is about 70 to 80 mμ in diameter and can be seen in the electron microscope but is fragile and never has been purified to any extent or analyzed chemically The cells from tumors all yield virus (Rubin, 1955) but at a slow rate, the average being something like one virus particle per 100 cells per hour. A most interesting point is its susceptibility to x-ray and ultraviolet irradiation, in which it differs radically from other animal viruses It has a sensitivity like other viruses to x-ray but *extraordinary resistance* to UV (Rubin, personal communication) This pattern of reaction is like that of the temperate viruses, and this behavior in respect to resistance to UV is interpreted with phage as being due to homologies between host and virus genetic substances, permitting rapid replacement of injured virus nucleic acid This type of radiosensitivity, the very narrow host range of the virus and the fact that RSV-infected fibroblasts divide is the best evidence which exists so far for some sort of provirus in the animal virus world

Rous sarcoma virus produces tumors with difficulty, if at all, in such related species as ducks, pheasants, etc It readily infects the chorio-allantoic membrane where it is capable of inducing both mesothelial and endothelial tumors (Rubin, 1955) Recently, it has become possible to infect chick fibroblasts in monolayers with production of plaques of tumor cells (Manaker and Groupé, 1956, Rubin, unpublished experiments)

Our knowledge of the serology of the virus is not very satisfactory. It can be neutralized by specific antiserum in the absence of complement But practically all barnyard fowl have antibodies to the virus, and the level increases with age Since this is the only host for the virus, neutralization tests have been complicated If a bird bears a virus-type sarcoma, the circulating antibody level is reduced, but, if the tumor is slow-growing or regressing, the blood level may be high The serology of the virus as tested on the chorio-allantoic membrane is straightforward

The vast majority of spontaneous fowl tumors cannot be passed directly by means of filtrates However, if the spontaneous tumor is first passed from bird to bird by means of whole cells, many become altered, so that filtrates are infectious In carcinogen-induced tumors of fowl this ability to be passed by filtrates does not occur even with prolonged transfer

There is no doubt about a causal relationship between virus and tumor in the case of the Rous sarcoma virus The response to the virus is rapid, a specific type of tumor is produced, and tumor induction can be obtained in vitro There are many other tumors of chickens, such as malignant lymphoma and leukemia, which involve the blood-forming organs, and these too are caused by viruses Some of these viruses, such as the one which causes malignant lymphoma, are very widespread in the normal fowl population, and there is evidence that the virus may spread through the egg

Kidney Tumor of the Leopard Frog. The leopard frog, which has a wide distribution throughout the continent of North America, frequently develops a spontaneous carcinoma of the kidney The tumor is quite malignant (Lucké, 1938) and may be maintained in frogs by grafting Filtrates of tumor will produce the disease, and the tumors contain small particles which, in section, appear to

in the medium to reduce greatly the probability of cell-to-cell transmission of infection (Vogt and Dulbecco, 1958). A similar situation can be demonstrated with NDV and HeLa cells (Ciecura et al, 1957; Puck, personal communication), in which case a large portion of the growing cells were shown to carry virus even in the absence of antibody The cells were not the wild type and were more difficult to infect than the normal ones. This infection, too, could be cured by antibody

These experiments with isolated cells so far emphasize the possible importance of circulating antibody, of persistent, slowly progressing infection, and selection of partially resistant host cells as possible factors in persistent virus infection

Latency in Plant Virus Infections Latency of infection in plants is characterized by the presence of virus unaccompanied by or with reduced symptoms. The classic example is the King Edward potato which is propagated vegetatively, is always full of virus but appears to be normal. When the potato is raised from seed, it does not contain the virus.

Some plants wither after infection but, before dying, send out new shoots which appear to be healthy These new tissues contain a reduced amount of virus and cannot be superinfected, but the reason for this immunity is not clear.

Virus Latency in Insects. Latency in insects is poorly understood because of poor titration technics for insect viruses It is quite common for epizootics to break out and decimate old laboratory-grown insect colonies, even after years of apparent health Apparently, some chemicals can act as inducers (Bergold, 1953)

VIRUSES AND TUMOR FORMATION

The importance of viruses in the etiology of malignant tumors has only gradually come to be widely recognized The increased importance of the virus theory stems both from research on tumors as well as from the development of virology. There is now an impressive group of tumors in which a virus plays an obvious role Oncologists are more interested than formerly in genetic changes, such as mutation, as a factor in cancer etiology, and the bacterial virologists have furnished clear-cut examples of the ways in which viruses can induce heritable changes in cells

The suggestion that tumors might have an infectious etiology was given substance by Rous (1911) with the discovery that filtrates of chicken tumors had the capacity to induce tumor formation in injected fowl The idea of a viral etiology for tumors did not go unchallenged It was said that chicken tumors were atypical tumors, that the viruses were passengers rather than inciters of the disease and, when similar agents were not found shortly in mammalian cancers, interest in virus etiology receded

Attention was turned to cancer induced by tars and other chemicals. After the isolation and the synthesis of carcinogenic compounds from coal tar was accomplished, a great number of other pure substances were found which were carcinogenic, yet the mechanism by which cancers were induced remained obscure A number of strongly carcinogenic chemicals were found to be potent mutagens as well Ultraviolet light and x-rays also have this dual capacity, and it has long been known that cancer cells show marked disorder of the normal chromosome structure. These facts and the obvious heritable character of the cancerous quality in cells have contributed to a revival of interest in the theory that cancer is due to something like somatic mutation This view does not exclude the possibility that *either* chemical agents or viruses could act as the mutagenic agent under different circumstances

Virus studies in other fields have provided sufficient evidence about the behavior of viruses, especially bacterial viruses, to make the case for virus etiology of tumors a plausible one As recounted under the section on latent virus infections and in the chapter on bacteriophages, there are a number of examples of lysogeny in which the virus persists in the cell in nonvirus form through an indefinite number of cell replications without ever being detected in the active form Such a prophage may cause the phenotype of the host cell to change (production of new antigens or new toxins) in quite definite heritable ways Nothing inherently different is required of tumorigenic viruses except that the ways in which

tive to ether. It is antigenic in rabbits, producing sera of weak or dubious neutralizing value It appears to be nonantigenic in mice It never has been purified or characterized chemically to any satisfactory degree It appears to multiply on passage in eggs, but the virus does not lend itself to accurate titration

The agent in milk (or from other organs) can cause breast cancer in mice by feeding, if fed in the early part of life, but the specific effect does not occur for many months (8 to 20, depending on the mouse strain) During this latent period there is no evidence of infection, and efforts to shorten the latent period have been unsuccessful In mice that are susceptible to the agent, the virus appears not only in the breast and the breast tumor but also in many other organs as well as in the blood However, it does not infect in utero The virus may reproduce in and be carried by strains of mice in which the incidence of cancer is low

At least two other factors are essential for the virus to be able to express itself in inducing cancer One is a hormonal effect (Huseby et al, 1946) Mammary carcinoma has a low incidence in the male If a male is castrated and then given estrogenic hormone, the susceptibility to virus-induced cancer becomes much greater If the male mice are of a high cancer line, the presence of virus plus hormonal treatment will cause an incidence of tumors equivalent to that in the virus-infected female In the absence of the virus, the tumors do not appear. Also, males of the low line show no tumors unless the virus is present

A second auxiliary effect is the genetic character of the host The virus, given to susceptible mice, produces a high incidence In low cancer (resistant) mice (Dmochowski, 1948), the incidence remains low In hybrids, the results are sometimes intermediate The resistance is further shown by the fact that virus given even in adulthood to susceptible mice will increase the incidence of cancer, while it has no effect in resistant adults It is clear, too, that the hormonal effect may be controlled genetically

The agent has been found naturally in a number of high-incidence inbred lines It has not been found in low-tumor lines (Dmochowski, 1951) The removal of the virus from a population by fostering lowers the cancer incidence markedly, but there remains a core of unaffected tumors The nature of this residue is unclear Histologically, the tumors in the low-cancer line are not very different from those occurring as a result of the milk factor. It has not been possible to demonstrate a maternal factor in the transmission of these low-incidence tumors, and no filterable agent has been obtained from them which incites tumor formation However, it cannot be ruled out that they are virus-induced, and perhaps only the proper means of demonstrating the agent is lacking, or the "provirus" may be defective and unable to produce a mature form

In summary, a high proportion of the mammary carcinomas which occur in high-tumor mouse lines is due, in part at least, to a virus The physical characteristics of the agent are as yet poorly defined The agent normally enters the newborn mouse with maternal milk and causes an infection which may involve a great many organs, but this infection has no detectable manifestation until fairly late in the life of the animal A certain genetic constitution, the details of which are not clear, and certain hormonal conditions, as well as the presence of the virus, are necessary for the tumor to appear These peculiarities of virus behavior the early symptomless infection, the long latent period and the need for specific genetic and physiologic conditions, and the production of a classic neoplasm have gone a long way in dispelling the prior objections to the virus etiology of tumors

Mouse Leukemia In addition to a wide array of tumors, mice also suffer from a number of blood dyscrasias, particularly leukemias The leukemias are now widely regarded as another type of malignant tumor. Lymphatic leukemia has been especially well studied in mice, and strains of mice have been developed through selection and inbreeding in which the incidence of spontaneous leukemia is as high as 95 per cent One such strain is called the A-K line

Mouse leukemias have frequently been studied by grafting cells from leukemic to nonleukemic animals and, when this has been done successfully, the disease develops in the recipient within a relatively short time In very young mice, an exceedingly acute and rapidly fatal disease is produced The trans-

be very much like viruses in structure (by electron microscopy)

Papillomatosis of Rabbits. For many years, the only clear-cut examples of virus-induced tumors were those of domestic fowl until Shope (1933) described the isolation of a virus from naturally occurring papillomas of wild North American rabbits The papillomas are nonmalignant, warty-type growths which appear on the ears and the backs of rabbits, and sometimes these excrescences are considerably cornified If the tumors are ground, filtered and titrated by inoculation into the skin of either wild or domestic rabbits, tumors are induced In the wild rabbit, these are full of virus, while in the domestic rabbit, little or no virus is found If the cells of these tumors are stained with fluorescent antiviral antibody, the virus is seen to exist mainly in the *nuclei* of the cells of the keratohyaline layer of the dermis (Noyes and Mellors, 1957) In domestic rabbits, the amount of virus found by this method is small When domestic rabbit tumors are transferred to other domestic rabbits by grafting, the host rabbits develop antiviral antibodies, showing the existence of virus antigens in the tumor Shope has described the virus in the domestic rabbit as being in a masked condition, although virus may simply be there in very small quantity (Beard, 1956)

Virus-induced papillomas are usually benign growths, but, after long periods of time (Rous and Beard, 1935, Kidd and Rous, 1940), they may become highly malignant and metastasize At this stage, virus cannot be detected in the tumor directly, but if the tumor is grafted onto a new host by means of whole cells, the new bearer responds by developing antibodies against the virus, showing continued presence of the antigens in the tumor That the virus (or antigen) is not necessary for continued malignancy is shown by the fact that, after prolonged transfer from rabbit to rabbit by whole cells, all serologic evidence of a virus being present may be lost (Rous et al , 1952), while the malignant characteristics of the tumor remain unchanged

Still another type of virus-induced tumor of rabbits is the fibroma (Shope, 1932) After inoculation of this agent, fairly typical and rapidly growing fibrous tumors are formed However, these are purely benign tumors, and they frequently regress and disappear spontaneously. Sometimes the virus from these regressing tumors also shows changes and will subsequently induce only a mild inflammatory disease in other rabbits. Because of these vagaries, this tumor will not be considered further. It may also be noted that this virus is related serologically to the agent causing myxomatosis in rabbits Berry and Dedrick (1936) found that heat-killed myxoma virus has the capacity, when injected with live fibroma virus, of permanently affecting the genotype of the latter, and it modifies the type of tumor produced in the direction of the tumor from which the heated extract was obtained

Up to this point it was frequently said that the virus-induced tumors were a different class of neoplasm than those which are not virus-induced The discovery of a viral agent from mouse mammary cancer was notable because this was a classic neoplasm Mammary cancer had been long studied from the genetic standpoint to determine the mode of its inheritance Little and his associates (Murray and Little, 1936) at Bar Harbor selectively inbred mice and obtained lines of animals which had a high and a low incidence of spontaneous mammary cancer They observed that, when these high and low cancer strains were crossed, the incidence of tumors in the offspring was greater if the mother, rather than the father, was from the high tumor line This maternal effect could be explained in three ways: it was a transfer of cytoplasmic factors by the ovum, an effect in utero, or something transferred in the milk Bittner (1936) found evidence for the early transfer of virus through the milk It was found that, if the offspring from a high cancer mother were removed immediately after birth and foster-nursed by a low cancer mother, the incidence of cancer in the offspring would be low, of the same order as the low line However, the contrary experiment of weaning offspring of low-line mothers to high-line foster mothers did not produce a dramatic rise in the expected incidence of breast cancer

Bittner showed that it was an agent in milk which had this effect The agent (Dmochowski, 1953) as it exists in milk is of unknown size but is sensitive to heat (inactivated at 60° C. for 30 minutes), and it is insensi-

tive to ether. It is antigenic in rabbits, producing sera of weak or dubious neutralizing value. It appears to be nonantigenic in mice It never has been purified or characterized chemically to any satisfactory degree It appears to multiply on passage in eggs, but the virus does not lend itself to accurate titration

The agent in milk (or from other organs) can cause breast cancer in mice by feeding, if fed in the early part of life, but the specific effect does not occur for many months (8 to 20, depending on the mouse strain) During this latent period there is no evidence of infection, and efforts to shorten the latent period have been unsuccessful In mice that are susceptible to the agent, the virus appears not only in the breast and the breast tumor but also in many other organs as well as in the blood However, it does not infect in utero The virus may reproduce in and be carried by strains of mice in which the incidence of cancer is low

At least two other factors are essential for the virus to be able to express itself in inducing cancer One is a hormonal effect (Huseby et al, 1946) Mammary carcinoma has a low incidence in the male If a male is castrated and then given estrogenic hormone, the susceptibility to virus-induced cancer becomes much greater If the male mice are of a high cancer line, the presence of virus plus hormonal treatment will cause an incidence of tumors equivalent to that in the virus-infected female In the absence of the virus, the tumors do not appear Also, males of the low line show no tumors unless the virus is present

A second auxiliary effect is the genetic character of the host The virus, given to susceptible mice, produces a high incidence In low cancer (resistant) mice (Dmochowski, 1948), the incidence remains low In hybrids, the results are sometimes intermediate The resistance is further shown by the fact that virus given even in adulthood to susceptible mice will increase the incidence of cancer, while it has no effect in resistant adults It is clear, too, that the hormonal effect may be controlled genetically

The agent has been found naturally in a number of high-incidence inbred lines It has not been found in low-tumor lines (Dmochowski, 1951) The removal of the virus from a population by fostering lowers the cancer incidence markedly, but there remains a core of unaffected tumors The nature of this residue is unclear Histologically, the tumors in the low-cancer line are not very different from those occurring as a result of the milk factor It has not been possible to demonstrate a maternal factor in the transmission of these low-incidence tumors, and no filterable agent has been obtained from them which incites tumor formation However, it cannot be ruled out that they are virus-induced, and perhaps only the proper means of demonstrating the agent is lacking, or the "provirus" may be defective and unable to produce a mature form

In summary, a high proportion of the mammary carcinomas which occur in high-tumor mouse lines is due, in part at least, to a virus The physical characteristics of the agent are as yet poorly defined The agent normally enters the newborn mouse with maternal milk and causes an infection which may involve a great many organs, but this infection has no detectable manifestation until fairly late in the life of the animal A certain genetic constitution, the details of which are not clear, and certain hormonal conditions, as well as the presence of the virus, are necessary for the tumor to appear These peculiarities of virus behavior, the early symptomless infection, the long latent period and the need for specific genetic and physiologic conditions and the production of a classic neoplasm have gone a long way in dispelling the prior objections to the virus etiology of tumors

Mouse Leukemia. In addition to a wide array of tumors, mice also suffer from a number of blood dyscrasias, particularly leukemias The leukemias are now widely regarded as another type of malignant tumor Lymphatic leukemia has been especially well studied in mice, and strains of mice have been developed through selection and inbreeding in which the incidence of spontaneous leukemia is as high as 95 per cent One such strain is called the A-K line

Mouse leukemias have frequently been studied by grafting cells from leukemic to nonleukemic animals and, when this has been done successfully, the disease develops in the recipient within a relatively short time In very young mice, an exceedingly acute and rapidly fatal disease is produced The trans-

mission of leukemias in this way is similar to the propagation of solid tumors by grafting. Immune tolerance factors in the recipient play a role The leukemias transfer readily only to closely allied strains or better to an inbred line of the donor variety.

In recent years (Gross, 1956), a way has been found to transfer the disease from one animal to another by means of filtrates of adult leukemic tissue. It is necessary to inoculate the filtrates into newborn mice, not more than 12 hours old, if the virus is to have any effect. The leukemia then appears in mice (even in strains with a normally low incidence of the spontaneous disease) but it appears only after many months The type of disease is that found in the donor mouse

There are several obvious similarities to the behavior of the milk factor. The virus must be given early to be effective It does not produce any overt disease for many months The effect of genetic constitution of the mouse on the outcome is also clear, inasmuch as some strains of mice give a much higher number of takes than others. Relatively little is known about the physical characteristics of the virus

In recent years, several other tumors of viral etiology have been found in the mouse When cell-free extracts of mouse leukemia cells are prepared (Gross, 1955, Stewart et al, 1957) and inoculated into very young mice, other tumors sometimes appear, such as primary tumors of the parotid, the submaxillary gland and other organs, indicating the presence of other tumor-producing agents Friend (1957) recently described a virus which produces leukemia in adult mice

For the few tumors of proved virus etiology, there are great numbers of tumors in which very extensive efforts to prove such an etiology have failed The reason for the failures may be that the tumors do not contain viruses, and viruses have nothing to do with their origin, or it is possible that a virus-inciting agent is of such subtle nature that ways have not been found to demonstrate it. Some of the difficulties of virus demonstration may be seen in the foregoing examples. It has been pointed out repeatedly that the tumors obtained with papilloma virus in domestic rabbits would pass as nonviral in origin if the domestic rabbit were the only experimental host.

There is no longer much question about the cause and effect relationship between some viruses and certain tumors. The causative agent has all the attributes of a virus. Its effect on the cell in the case of the Rous sarcoma virus is direct, rapid and specific. There is no other postulated agent which has these properties As was noted in the beginning of this section, there is also evidence from other sources to indicate that a virus can have a profound effect on the functional properties of the cell, especially when it is the type of virus which does not destroy the cell We can think of tumorigenic viruses as being analogous to the temperate rather than the virulent bacteriophages The action of initiating cancerous growth could be due to a disturbance of the normal cellular genetic apparatus Once initiated, it is not necessary to postulate continued presence of the virus to maintain the condition, although it may be there in provirus form. It is not necessary to assume that only a virus could have this same disturbing action on the cell Thus, in accepting the virus theory of the origin of cancer, it does not appear to be necessary to accept it as an exclusive theory. The investigation of tumor viruses is really just beginning and, with the advent of new tissue culture technics, it is not a wild speculation to guess that discoveries in this field will be of even greater interest than those with the viruses which cause acute necrosis and cell death

Interference

INTRODUCTION

In the course of laboratory investigations of different virus diseases, situations inevitably arose in which a host was exposed to simultaneous infection with two viruses In several instances, accidental or deliberately contrived, it was found that infection with one virus mitigated the severity of disease produced by the other This phenomenon, unrelated to conventional immunologic reactions, bore superficial resemblance to certain types of cross-protection in mixed bacterial and parasitic infections of animals and was thought to be due to mutual "interference" between the two viruses involved

Because of the intimate dependence of viruses on the susceptible cell as a medium for propagation, it was assumed that interfering and suppressed viruses somehow competed for the same cells, and that a cell could not support the simultaneous replication of two viruses. This simple interpretation did not stand up under experimental test Instead, it has been found that concurrent infection of a host or even a single cell with two different viruses can express itself in a number of ways (1) both viruses multiply side by side and produce independently characteristic manifestations of infection (*dual infection*), (2) the viruses undergo some sort of genetic interaction and produce progeny with new properties (*recombination*), (3) one virus so modifies cells or the tissues of a host that a second one cannot multiply normally or cannot produce characteristic injury (*interference*) In addition, some effects have been reported, such as "exaltation," which require further clarification before they can be characterized within or outside of this framework. These various relationships can be demonstrated in mixed infection not only with two unrelated viruses but also with different mutants of the same virus, provided that the infecting dose is large enough to permit invasion of single cells by more than one particle. Altogether, quantitative factors are of paramount importance in determining whether a given set of circumstances will lead to the production of interference or alternate manifestations of mixed infection

EXPRESSIONS OF INTERFERENCE

Interference may be defined by two parameters: (1) inhibition of multiplication of one virus in a host system simultaneously infected with another virus, (2) suppression of injury, disease, or death due to one virus by simultaneous infection with another. From the point of view of possible medical significance, the latter is perhaps of more immediate interest In experimental systems, however, inhibition of viral multiplication is often the only observable effect, and it is on such systems that mechanisms can best be studied.

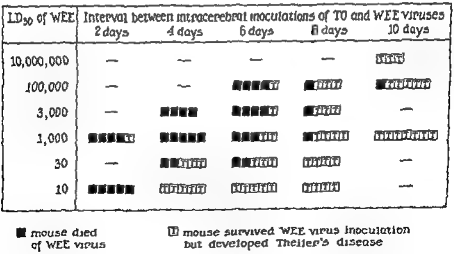
INTERFERENCE WITH DISEASE PRODUCTION IN EXPERIMENTAL ANIMALS

Historically, it was the suppression of disease or death in already infected animals

which first called attention to the existence of a mechanism of host resistance to viral infection other than classic humoral or nonspecific forms of immunity. Although occasional hints at interferencelike cross-protection can be traced to early clinical empiricism or experimental work, clear recognition of the specialized aspects of interference has come relatively recently For a comprehensive review of the subject see Henle (1950) The following examples have been selected arbitrarily to illustrate the diversity of experimental systems involving interference

Interference Between Unrelated Viruses. In 1937, Dalldorf, Douglass and Robinson reported that monkeys infected with lymphocytic choriomeningitis virus failed to become paralyzed when superinfected with poliovirus This type of protection lasted about 2 weeks, and after 1 month full susceptibility to poliovirus was restored Because of the transitory nature of resistance and because the 2 agents were not antigenically related, this sparing effect was considered to be a new immunity mechanism in the virus field Dalldorf et al also observed that spinal cords of doubly infected monkeys did not contain as much virus as those of polio-infected control animals.

Subsequently, similar observations were made with a variety of other viral combinations The dependence on timing and dosage of the effectiveness of interference was illustrated by experiments with the TO strain of Theiler's virus (*poliovirus muris*) and Western equine encephalomyelitis (WEE) virus (Schlesinger et al , 1943) Intracerebral inoculation of the TO virus induces in mice, after an incubation period of about 2 weeks, a paralytic disease of the poliomyelitis type. The virus multiplies to a titer of about $10^{3.5}$ ID_{50} WEE virus, on the other hand, causes a rapidly fatal form of diffuse encephalomyelitis and attains titers of the order of 10^{9} LD_{50} Figure 42 illustrates what happens when mice are infected with both viruses If TO virus is injected intracerebrally immediately before or together with minimal amounts of WEE virus, all mice succumb to the latter. If TO virus is given first and followed after increasing intervals by WEE virus, progressively larger amounts of the latter are required to bring about infection At 10 days, the mice resist as much as 10



experiment)

million lethal doses of the far more virulent equine virus. Even after inoculation of such excessive doses, no multiplication of this virus is demonstrable. In contrast, the course of Theiler's disease is not affected by the interposed inoculation of WEE virus, and the increasing protection can be correlated directly with the multiplication and the progressive spread of TO virus within the central nervous system.

In other systems it has been found that the interfering virus need not be pathogenic or capable of unrestricted multiplication. Multiplication of egg-adapted strains of influenza virus in mouse brain is known to be restricted to a single cycle yielding abnormal, noninfectious virus. Vilches and Hirst (1947) have shown that such strains, inoculated intracerebrally, nevertheless protect mice against the lethal effects of various encephalitic viruses, e.g., WEE virus. In this case, the interfering agent has to be given either within 2 weeks before or together with the suppressed virus. Since the interfering infection is not progressive, effective interference depends on initial administration of massive doses of influenza virus.

The same requirement for saturating doses applies in those cases in which successful interference with virulent agents is exerted by *inactivated* viruses. For example, Vilches and Hirst (1946) have found that ultraviolet-irradiated influenza virus retains at least part of its capacity to protect mice against WEE virus. The effect of inactivation will be discussed more fully in a later section.

Interference by Avirulent with Virulent Variants of the Same or Related Viruses. Results obtained when immunologically related viral pairs are inoculated together or consecutively in animals are much more difficult to interpret as interference than the previously described examples, because the operation of specific humoral immunity mechanisms must be ruled out. The observation by Hoskins (1935) of protection against viscerotropic yellow fever virus by simultaneous inoculation of a neurotropic variant is a case in point. the strongest argument against the role of antibody in this system stemmed from the later finding (Findlay and MacCallum, 1937) that neurotropic yellow fever virus similarly protected against the serologically distinct Rift Valley fever virus.

A classic observation by Magrassi (1935) concerned the competition (*Konkurrenzphänomen*) between 2 doses of herpes simplex virus given by different routes of inoculation. For example, subcutaneous injection of herpes virus in the abdominal wall led to ascending myelo-encephalitis with death, usually in the second week. Intracerebral infection, in contrast, killed rabbits after 3 to 4 days. When intracerebral reinfection followed primary subcutaneous inoculation by about 7 days, animals were protected—the 2 lethal doses had canceled each other out. This was not effective with either shorter or longer intervals. The protection seemed to be strictly limited both in area and in time. This example and a number of modifications reported by Magrassi and later by Doerr and co-workers seem to illustrate a combination of interference and of local, specific immune mechanisms.

An interesting manifestation of interference, and one of importance in connection with adaptation of viruses to new experimental host systems, has come to the fore in recent years with the increased use of mice for attenuation of viruses by intracerebral serial passages. In the course of such passages, virulence for the mouse (neurotropism) may develop gradually, presumably as a result of multiple mutational steps and of selective advantage of the virulent mutants. When unadapted or partially adapted viruses are titrated in mice the mortality rate is often higher among those inoculated with small than with large doses of viruses. Such paradoxical titrations have been seen in work with several viruses, e.g., yellow fever, Rift Valley fever and dengue viruses. In the last case, it was found that viral populations giving paradoxical effects on titration were mixtures of avirulent and virulent particles in proportions permitting the former to block the latter at high, but not low, concentrations (Schlesinger, Frankel, and Winter, to be published). This type of phenomenon is called "auto-interference."

Interference with Cytopathogenic Effects in Tissue Cultures

The development of tissue culture systems suitable for quantitative study of viruses has made possible the demonstration of interference at the cellular level divorced from immune mechanisms of intact host animals

Qualitatively, interference in metabolizing tissue fragments had been shown earlier for different strains of influenza virus (Andrewes, 1942) and for a variety of neurotropic viruses (Huang, 1943; Lennette and Koprowski, 1946). Indeed, Huang, in his studies on interference, used the metabolic inhibition which was reintroduced later for extensive use in neutralization tests with poliovirus. He showed that cell destruction by certain viruses (e g., WEE) could be detected by adding an indicator dye to the liquid medium. Normally metabolizing tissue produced acid with a resulting color change, while destructive viruses prevented such a change Using this criterion, he was able to demonstrate interference between nondestructive (St Louis encephalitis) and destructive (WEE) viruses

Recognition of specific cytopathogenic effects as an expression of virulence, and introduction of the plaque assay technic for quantitation of animal viruses have significantly refined work on the mechanism and the dynamics of interference. Various studies utilizing these phenomena for analyses of interference with homologous or heterologous viral combinations have shown that the protective function of an interfering virus, whether active or inactivated, can be demonstrated in tissue cultures as convincingly as in animals Some of these investigations which have furthered our knowledge on the general characteristics and mechanisms of interference will be discussed more fully in the appropriate later sections

Interference with Multiplication of Influenza Virus in the Chorio-allantoic Membrane of Chick Embryos (CAM)

Use of the influenza virus-CAM system as a model for work on fundamental aspects of viral infections offers these advantages: (1) viral multiplication can be demonstrated and quantitated even in absence of death or injury to the host by measuring titers of viral hemagglutinin (HA) or complement-fixing antigens (S or V antigen); (2) the viral yield can be determined quantitatively as well as qualitatively in terms of its infectious titer relative to its HA titer (ID/HA ratio), with low ratios indicating preponderance of noninfectious hemagglutinating (incomplete) virus; (3) virus is liberated by infected cells into the allantoic fluid (AF), and thus separation of extracellular viral particles from virus associated with cells is facilitated; (4) this system can be improved still further by deembryonation, which eliminates all contents of the egg other than the CAM, or by maintenance of surviving CAM fragments in defined media; (5) the role of viral enzyme and its mucoprotein substrate (cellular receptors) in adsorption of viral particles has been established, and adsorption can be blocked by receptor-destroying enzyme (RDE of *V. cholerae*); (6) interaction of strains (interference, dual infection, genetic combination) can be investigated because multiple genetic markers are available for easy identification of yields (e g , serologic specificity, virulence for mice or chick embryos, enzymatic activity, heat stability)

Application of these technical aids to investigations on interference has yielded many important findings, especially with regard to the fate of interfering and suppressed virus Mutual interference between active A and B strains of influenza virus was demonstrated in 1944 by Ziegler and Horsfall. When relatively small amounts of each type were inoculated simultaneously, both multiplied When one had a head start of 8 to 12 hours, the other one was suppressed, unless it was given in excessively large doses

Subsequent experiments by Burnet and Hirst and their co-workers on genetic recombination between different strains of influenza virus have confirmed that one strain of virus, given the proper advantage, can block multiplication of another This works for heterotypic (A vs. B) as well as for homotypic pairs distinguishable by strain-specific antigens or various other attributes. On the other hand, when the same pairs are inoculated in equivalent amounts, the progeny may include many viral particles containing genetic or nongenetic markers contributed by both parent strains. Since such genetically or phenotypically mixed particles must arise in cells in-

fected with both parent strains, it is clear that interference between 2 active influenza viruses at the cellular level is not an absolute all-or-none phenomenon, but that it occurs only under special conditions

The situation is somewhat more clear-cut when *inactivated* virus is used as the interfering agent. It was first reported by Henle and Henle (1943) and Ziegler et al (1944) that ultraviolet-irradiated virus, when inoculated in large doses into the allantoic cavity, inhibited the propagation of active influenza virus of either the homologous or the heterologous type Inhibition occurred when the irradiated virus was given simultaneously with or as long as 96 hours (longest interval tested) before inoculation of the active virus Interference was obtained even when the inactivated virus was given shortly *after* the active virus, *i e*, *before newly produced progeny* of the latter had appeared Under these conditions, homotypic irradiated virus completely inhibited multiplication, while heterotypic virus permitted it to proceed in those cells already infected with active virus By the use of heterotypic irradiated virus it was possible to obtain one-step growth curves for influenza viruses (Henle et al, 1947) That is to say that spread of newly produced virus to primarily uninfected cells was prevented by the blocking action of the inactivated virus

The Relation of Incomplete Virus Production to Interference

Another basic observation concerns the demonstration of auto-interference in eggs inoculated with large amounts of influenza virus This manifests itself in the form of release of noninfectious hemagglutinating virus (incomplete virus) Under standard conditions, when eggs are inoculated with dilute viral suspensions (e g, 10^{-4} diluted infected AF containing 100 to 1,000 ID_{50}), the viral progeny harvested at about 40 hours has an ID/HA ratio of around $10^{6}/1$ to $10^{6.5}/1$ * Such standard viral populations contain, on the average, about 10 virus particles per infectious unit, as determined by electron microscopic particles count, HA titrations and chemical analysis (Isaacs, 1957). Hence, by definition, 9 of every 10 viral particles may be classified as noninfectious. The proportion of noninfectious virus is greatly increased in AF harvested from eggs inoculated with undiluted standard virus containing more than 10^{5} ID_{50} Horsfall (1954) and Paucker and Henle (1955) have shown that this phenomenon can be further enhanced by using as seed inoculum virus which has been heated at 37° C. for several days and thus has acquired a much reduced *ID/HA* ratio.

Von Magnus reported in 1951 that serial egg-to-egg transfer of undiluted infected AF (*undiluted passage series*) yielded virus of increasing incompleteness, i e., decreasing ID/HA ratio The lowest ratio of 10/1 to 100/1 was reached in the third or fourth undiluted passage, this ratio indicating that only about 0.00001 to 0 000001 per cent of the viral progeny was infectious HA titers in such yields rose to normal or nearly normal levels, suggesting that viral propagation as such was not suppressed. Nevertheless, this progressive qualitative change in properties of the virus has been interpreted as interference with production or maturation of normal virus resulting from overloading of cells at the time of infection While it seems reasonable to postulate that the low yield of infectious virus may be due to interference by noninfectious with infectious virus, the role of this mechanism in the genesis of the incomplete virus itself remains problematical For example, it has been reported that incomplete virus can be obtained in eggs infected with relatively small doses of virus, and the same may be true for another host tissue, viz, mouse brain, in which the multiplication of certain influenza strains is restricted to a single cycle yielding incomplete virus (Schlesinger, 1950, 1953) The subject is discussed in further detail in Chapter 4

GENERAL CHARACTERISTICS AND INTERPRETATION OF INTERFERENCE PHENOMENA

Interference as a Localized Phenomenon. Critical quantitative findings in tissue cultures have pinpointed the individual cell as the site of the phenomenon. This conclusion is in line with earlier studies which have clearly shown that protection by interference is not associated with a systemic change in

* It should be pointed out that this ratio holds true only if the HA titration is carried out under standardized conditions with approximately $10^{7.2}$ RBC per agglutination tube Reduction in the number of RBC would lead to a corresponding increase in HA titer, since the titer is that dilution of virus at which the number of viral particles roughly equals the number of RBC (Isaacs, 1957)

the intact host's response to the suppressed virus, but that it is limited to those tissues or cells which have had contact with the interfering agent Thus, when an interfering dose of ultraviolet (UV) irradiated influenza virus is inoculated into the allantoic cavity of embryonated eggs, the amniotic sac retains *susceptibility to infection with active virus* (Henle, Henle, and Kirber, 1947) The same principle probably applies to several observations in which protection against neurotropic viruses was limited to the neural pathway already traveled by another virus

Nature of Interfering Agents The interfering capacity has always been found to be inseparable from the viral particles themselves, except for a very recent observation suggesting the liberation of a nonviral interfering compound from cells exposed to inactivated influenza virus (see below, *Mechanisms of Interference*) *If the interfering* virus is noninfectious in the sense that it is incapable of detectable multiplication, it nevertheless contains specific antigens or possesses some other viral properties such as, in the case of myxoviruses, the ability to agglutinate erythrocytes That the interfering capacity is independent of reproductive capacity is illustrated by the fact that UV- or heat-inactivated *myxoviruses are potent interfering* agents In some instances, the interfering virus is restricted in its multiplication either because it is not adapted to the particular host system (e g, influenza virus in mouse brain) or because of the intervention of other factors, such as specific humoral immunity All available evidence indicates that effective interference depends on the native or residual ability *of the virus to interact in* some specific manner with the host cells Powell and Pollard (1956) have examined the effect of ionizing and monochromatic UV irradiation on the interfering property of influenza virus Their data suggest that the interfering capacity resides in a very small portion of the viral particle corresponding to a unit of about 2×10^6 A^3 in volume and molecular weight of *1,600,000 The action spectrum suggests* that the active moiety may be protein associated with the viral RNA, but a possible role of lipids has not been ruled out

***Time and Dosage Factors** Regardless* of its nature or of the particular way in which its interaction with the host cells manifests itself, the interfering virus, in order to be successful, must have a quantitative advantage or a head start over the virus that is to be suppressed Hence, if a mixture containing equal amounts of 2 viruses is inoculated into a host, chances are that the one which infects or multiplies more rapidly will predominate in the yield; or, if in a mixture one virus exceeds the other in amount, it will as a rule act as the interfering agent. By the same token, viruses which are restricted in their multiplication or have been inactivated must be administered in large doses in order to be effective as interfering agents In line with these general principles, the interfering virus must be given before, together with, or—other quantitative conditions being favorable—shortly after the virus which is to be suppressed

This intimate dependence on dosage and timing strongly suggests that the interfering *virus must saturate the susceptible cells and* must modify them in some manner. Thus, the number of cells lining the allantoic cavity has been variously estimated to total between $10^{7.2}$ and $10^{8.9}$, and maximally effective interference by *UV-inactivated with active influenza* virus in the CAM requires inoculation of about 10^8 to 10^9 viral particles. Even after such saturating doses of inactivated virus (multiplicity greater than 1 viral particle per cell) maximum interference is not established momentarily but only after some 16 hours (Fazekas de St. Groth et al, 1953; Paucker, 1958) During the intervening period, over-all viral multiplication is gradually retarded, and the yield is progressively lowered Kinetic data also suggest that in a certain proportion of the cells multiplication of superinfecting active virus is not blocked, no matter what the multiplicity of the inactivated virus

In this connection, the occurrence of genetically or phenotypically mixed progeny particles in eggs infected with different influenza strains clearly shows that the mere association of one viral particle with a cell [illegible]

certain proportion of the cells may yield recombinant progeny particles, indicating that the in[illegible]
ply by [illegible]
agent [illegible]
ent conflict between the concepts of interfer-

ence and of dual infection resolves itself if it is appreciated that viral populations, especially after partial inactivation by physical means, are undoubtedly inhomogeneous with regard to various biologic properties

Allowing for these qualifications, it can be concluded that interference by inactivated influenza virus may be induced in a single cell by effective combination with a single viral particle. This conclusion has received convincing experimental backing from studies by Baluda (1957) on the capacity of UV-irradiated Newcastle disease virus (NDV) to interfere with active NDV in monolayers of chick embryo lung cells In this system, the number of cells and the number of inactivated and of superinfecting active viral particles can be determined accurately, and the total yield of virus as well as the yield per cell can be measured by the plaque assay method Baluda's findings indicate (1) that *a single inactive particle per cell can induce interference*, (2) that *interference may be established in some cells within a fraction of a minute* A certain proportion of the cells which have adsorbed UV-irradiated virus can be superinfected with active virus provided that the multiplicity of the latter is high enough

Sensitive tissue culture methods have also been applied by Levine (1957) to a quantitative analysis of the mutual interference between active myxoviruses and WEE virus This system apparently differs from others in principle in that production of NDV in single cells can be diminished by superinfection with WEE virus as long as 5 to 6 hours after infection with NDV. At the same time, the ability of NDV-infected cells to produce WEE virus decreases exponentially with time after primary NDV infection In other words, there is a period after primary infection with NDV, during which superinfection with WEE virus results in multiplication of both agents, but to lower titers than in singly infected cells.

MECHANISM OF INTERFERENCE

An examination of facts known about interference makes it abundantly clear that it is localized in the individual cell Obviously, an understanding of mechanisms requires far more basic knowledge about viral reproduction than we now have What is particularly vexing is the diversity of viral combinations with which interference can be demonstrated

A consistent pattern has emerged from investigations into the events leading from exposure of a cell to virus to the ultimate release of viral progeny This pattern involves: (1) *collision* between virus and cell, requiring proper electrostatic forces and absence from the extracellular environment of inhibitory substances; (2) specific *adsorption*, the mechanism of which is understood only in the case of myxoviruses, (3) *penetration* into the cell; (4) *disintegration or loss of identity* of infecting viral particles, (5) *eclipse* period; (6) appearance in increasing amounts of *newly produced viral materials*, including antigens, hemagglutinins and, finally, infectious virus; (7) *release* of newly produced virus and viral products by gradual secretion or upon disintegration of the cells These processes may or may not be associated with recognizable histologic changes Use of histochemical methods, including fluorescein-labeled antibody and of electron microscopy, and physical separation of cellular particulates has refined study at the cellular level, especially the distinction between "nuclear" and "cytoplasmic" viruses. An imposing body of evidence is accumulating in support of the essential role of viral nucleic acid, especially RNA, as the genetic material of many animal viruses and of the idea that genetic and nongenetic viral constituents are replicated separately Beginnings have been made in the development of antimetabolites which are thought to inhibit (or promote) viral multiplication through their effects on biosynthetic processes, especially those concerned with nucleoprotein metabolism (Chap 6). Finally, certain substances, notably bacterial endotoxins, have been found to inhibit viral toxicity without significantly influencing viral reproduction

These various facets are recapitulated here (for more comprehensive discussion see Chap 4), because the key to the mechanism of interference clearly lies in an understanding of the fate of the interfering and the suppressed virus, of their effects upon the cell, and of the specific viral constituents responsible for the observed activities. Only rudimentary beginnings have been made in these directions

Perhaps the simplest concept could explain those examples in which progressive infection with one pathogenic virus induces increasing protection against another (Fig 42), one could simply postulate that the interfering virus has led to general, nonspecific damage

to or death of so many cells that the *second virus finds itself without a suitable medium.* This explanation fails to do justice to those cases where interference does not occur or is induced by avirulent, nonmultiplying, or inactivated viruses Here the clues have to be sought in terms of more specific and subtle relationships

The demonstration of *dual infection of single cells* with viruses producing intranuclear (herpes simplex) and cytoplasmic (vaccinia) inclusions (Syverton and Berry, 1947) perhaps suggests that interference may not occur between viral pairs utilizing for their replication different cellular matrices. One may look in the same light upon the fact that certain virus-induced tumor cells support the propagation of superinfecting unrelated viruses better than normal tissues and cells of the tumor-bearing animals.

On the other hand, some viral pairs which do display one-way or reciprocal interference are so far apart in their general biologic properties that it is difficult to imagine common factors involved in their genesis (influenza or NDV vs WEE virus). Yet, the recent work by Levine (1957) has shown that two such viruses can compete with one another in the individual cell with the result that the yield of each is reduced This finding, coupled with reaffirmation of earlier indications that destruction of cellular mucoprotein receptors by myxoviruses or RDE has no effect on the infectability of cells by WEE virus, would suggest that the *competition* may be *for cellular constituents needed for the synthesis of both viruses.*

Such direct competition appears to be more unlikely in systems utilizing *nonmultiplying* or *inactivated* viruses as interfering agents We may ask, first, what is the *fate of the interfering virus?* The most searching studies have been done with UV- or heat-inactivated myxoviruses in eggs (Henle, 1950) and tissue culture (Baluda, 1957) UV-irradiated influenza virus is *adsorbed* by the allantoic cells, and after a short period of time its interfering action can no longer be neutralized by antibody or released from the cell by RDE: it has *entered the cell.* In contrast, attachment of UV-irradiated NDV to chick embryo lung *monolayers remains* partially reversible by anti-NDV antibody in that such treatment prevents exclusion of superinfecting active virus in about 50 per cent of the cells This observation by Baluda suggests that interference follows upon superficial attachment of inactivated particles to the cell The contrast between the two systems may be fundamental but may also be due to physiologic differences between allantoic cells in the intact egg and epithelial lung cells in monolayers. The extent to which inactivated viruses can enter into an association with host cells may be revealed in future studies, especially with radioisotope-labeled virus.

However, the *maintenance of refractoriness* to superinfecting active virus appears to depend on continued association of interfering virus with the cell. In the NDV system, this association breaks down after 26 to 60 hours, and then the cells' susceptibility to active NDV is restored. The effect of UV-inactivated *influenza virus is longer lasting—perhaps* again suggestive of a more profound integration of the virus into the cell It should be remembered that UV-irradiated influenza virus has been shown to be reactivable in allantoic cells by active virus of a different strain, as indicated by the fact that from such doubly infected cells genetically mixed progeny particles can be obtained This would support the idea that at least a fraction of the irradiated virus can go beyond the stage of superficial adsorption A benzimidazole derivative (2,5-dimethylbenzimidazole) which is thought to inhibit the multiplication of influenza virus through its effect on the nucleic acid metabolism has been reported to prevent interference by inactivated influenza virus (Tyrrell and Tamm, 1955). In line with this is the suggestion offered by Powell and Pollard (1956) on the basis of irradiation experiments that retention of interfering capacity may depend on the integrity of a minute component of the viral particle, perhaps one associated with viral RNA

A high degree of integration of interfering virus into the cell may exist in several cases in which a long-lasting carrier state has been induced in *tissue culture cells surviving infection* with active virus (poliovirus, WEE, virus, NDV) Such cells have been found to resist superinfection with homologous or unrelated viruses. *A revealing study of this sort* concerns persistent infection of HeLa cells

with NDV (Cieciura et al, 1957) In HeLa cell cultures exposed to active NDV, less than 0 1 per cent of the cells survived, and these were grown to mass cultures From these, individual cells were removed and used to establish pure clones Clones were grown over a period of 2 years through hundreds of cell generations. The cells appeared quite normal but retained resistance to superinfecting NDV. When they were seeded on X-irradiated feeder layers of cells, they released active NDV which destroyed both themselves and the feeder layer Thus, it was shown that the original infection had been carried over from cell to cell without recognizable damage Superficially, this system suggests an analogy to lysogeny in phage-infected bacteria (Chap 7), but more recent evidence suggests that the carried virus is neutralizable by antiviral serum and thus located near the cellular surface rather than present in the form of provirus At any rate, the finding of resistance of these cells to superinfection again points to the *dependence of interference on the continued association of the interfering agent with the host cell*

If little is known about the fate of interfering viruses, even less can be said about the manner in which the interfered cell disposes of the suppressed virus For the most thoroughly studied systems, those involving myxoviruses, it has been found that (1) no virus-inhibiting substances are liberated by the cells into their environment, and (2) adsorption of superinfecting virus is not prevented Baluda's studies (1957) on NDV in tissue culture pretreated with UV-inactivated NDV have demonstrated that superinfecting virus disappears more rapidly than from normal cells That fraction which remains attached can be inactivated by antibody at a time when virus in association with normal cells would not be affected by such treatment because it has penetrated into the cells It has been suggested on the basis of these findings that active virus, after adsorption on interfered cells, is either *inactivated at the cellular surface* or prevented from *penetrating into the cell*. A recent provocative finding by Isaacs et al (1957) promises to clarify this aspect further These authors have reported that surviving fragments of allantoic membrane of chick embryos, exposed to heat-inactivated influenza virus and refractory to infection with active virus, liberate into the medium a macromolecular material (Interferon) which in turn can block infection of normal allantoic cells to which it has been added Interferon has no recognizable viral properties, is not neutralized by antiviral immune serum and cannot withstand heating at 60° C. for 1 hour The mode of its liberation suggests that it is a specific product of (abortive?) viral activity in the cell, but its biologic and chemical nature requires further study. It does not inactivate virus directly but acts only in conjunction with cells

It has been mentioned already that the *modus operandi* in certain other systems may be connected with more advanced stages of the infectious cycle, i e, that inactivation at the cellular surface or prevention of penetration of superinfecting virus do not account for the observed effects (e g, the lowered yields of both agents in single cells infected with NDV and WEE virus) In systems in which an avirulent variant protects a host against a virulent variant of the same or a related virus, it may be difficult to distinguish between true interference (i e., inhibition of multiplication of the virulent component) and multiplication of both, resulting in genetic recombination and dominant expression of the avirulent character

These considerations make it clear that mechanisms involved in interference may be as diverse as are the experimental observations interpreted as interference The complexities of the virus-cell interaction leave room for speculative analogies to a broad spectrum of biologic phenomena which may explain why the study of interference between viruses is of such dominant interest to many workers in the field. For example, in considering inhibition of penetration or surface inactivation of superinfecting virus, one may think of the restriction of fertilization to a single sperm and exclusion of others Mutual interference has also been demonstrated between different DNA preparations in the transformation of bacteria Considering the profound metabolic derangements which must accompany synthesis of viral materials, both genetic and nongenetic, in the infected cell, it is likely that mechanisms similar to those which can block or *modify constitutive* or

adaptive biosynthetic processes may play a role in competition between viruses. Finally, there are certain obvious analogies of interference between animal viruses to similar phenomena observed with bacteriophages. The basic concepts formulated from work on bacterial viruses are discussed fully in Chapter 7. They are an important guide in the interpretation of interference between animal viruses.

MEDICAL IMPLICATIONS OF INTERFERENCE

As long as relatively few viruses were known as human pathogens, and each disease they caused seemed to be either a self-limiting or a fatal episode, interference could be regarded chiefly as a laboratory oddity—an interesting if somewhat artificial tool for studies of the fundamental biology of viral infections But with the discovery of an ever-growing number of pathogenic and seemingly nonpathogenic viruses, the question of what might happen when a human being is exposed to mixed infection is perhaps not of purely academic interest but may prove to be of clinical importance as well This is suggested not only because the chance of acquiring concurrent infections grows with the number of possible risks but particularly in view of the mounting evidence indicating that viruses may persist and multiply in host cells for long periods of time without persistent pathologic consequences. A striking example of the latter phenomenon in man is the prolonged association of adenoviruses with adenoids and tonsils which must be inferred from the frequency with which they can be activated in cultures of these organs (Chap 29). It is almost certain that application of tissue culture methods will uncover similar relationships for other viruses and other organs.

There is as yet no direct proof for the hypothesis that such persistent infections of human cells may affect susceptibility to superinfecting viruses But under experimental conditions it has been possible to show, in a number of instances already mentioned, that carrier lines of cells are resistant to various active viruses This aspect offers a broad field for further exploration of immediate medical importance.

Apart from the possible protective role of a chronic carrier state, it seems unlikely that conditions favoring the establishment of effective interference would be often fulfilled in natural infection of man As has been discussed above, these conditions are highly specialized with regard to selection of suitable viruses, factors of dosage and timing, opportunity to infect the same cells concurrently. In order to interfere, two viruses would have to compete with each other either at the portal of entry or elsewhere in association with cells which both are able to infect Moreover, for interference to be effective as a protective mechanism, the entire or nearly the entire appropriate cell population would have to be involved. Therefore, it is small wonder that several pairs of viruses which are known to be capable of interfering in experimental hosts have been isolated together from individual patients. An example is the presence of Coxsackie and polioviruses in single stool specimens and concomitant demonstration of a simultaneous rise in antibody titers against both viruses in the patient's serum Interference between Coxsackie and polioviruses has been shown to occur in mice

That interference can exist in man under suitable conditions is illustrated by recent experimental work with dengue virus Simultaneous infection of human volunteers with attenuated yellow fever and active dengue viruses was followed by an attack of dengue much milder than in control patients infected with dengue virus alone. Specific cross immunity was not involved here, for yellow fever vaccine failed to protect against dengue virus given later It has also been found that the immunogenic effectiveness of two attenuated dengue strains and yellow fever vaccine is reduced when they are inoculated in the form of mixtures; depending on quantitative factors, antibody is produced against one to the exclusion of the other antigens Since the antigenic potency of these attenuated viruses seems to depend on their ability to multiply, it is likely that the failure to elicit a simultaneous immune response to each component is a result of interference (Schlesinger et al, 1956). This finding has obvious practical implications in view of the growing tendency to recommend a variety of attenuated viruses for immunization of man It should be noted

that *no* such mutual interference has been observed between inactivated viruses injected in the form of mixtures.

A further point of practical significance is the possible role of interference in vectors or intermediate hosts of human pathogens. For example, dengue and yellow fever viruses have been found to interfere in their common vector, *Aedes aegypti*, and interference between various arthropod-borne viruses belonging to Group A or Group B (Chap 12) has been demonstrated on numerous occasions in experimental animals or tissue culture It is conceivable that the geographic spread of these and other arthropod-borne viruses may be limited by such a mechanism, especially in view of the fact that insect vectors, once infected, remain so for the rest of their life.

Chemotherapy and Virus Infection

INTRODUCTION

At the present time no specific or effective therapy is available for virus diseases. Certain virus diseases can be prevented by immunization with infective or inactivated virus vaccines or by administration of specific antibodies. Moreover, in some infections administration of specific antibodies during the incubation period results in a milder form of disease. These preventive or modifying effects cannot be accomplished with any known drug. In contrast, numerous diseases caused by Chlamydozoaceae, rickettsiae, or bacteria can be effectively prevented or treated with appropriate drugs.

It is a matter of considerable theoretical interest as well as practical importance that highly effective antimicrobial compounds such as the tetracyclines fail to exert a beneficial effect in virus diseases except when secondary bacterial infection caused by drug-susceptible micro-organisms is present. Since not only viruses but also the Chlamydozoaceae and the rickettsiae are obligate intracellular parasites, the insusceptibility of viruses to present-day antimicrobial drugs cannot be due to this important biologic circumstance per se. The decisive difference between viruses on the one hand and Chlamydozoaceae and rickettsiae on the other presumably concerns the metabolic requirements and the intracellular conditions of multiplication of viruses in contrast with the larger agents. It is possible that the susceptibility of the larger agents derives from possession of some metabolic mechanism which the viruses, being smaller and simpler, lack. Possession of this hypothetical mechanism might endow the larger agents with a measure of independence from host cell metabolic activities and at the same time make them more vulnerable to selective inhibition.

Experimental studies in the laboratory involving thousands of chemical compounds and biologic materials have not yielded substances of sufficient promise to warrant a prediction that they might be useful in the treatment of human virus infections in the field. In fact, there is uncertainty as to whether potent and selective inhibitors of virus multiplication, if such were found, would prove to be useful in the treatment of virus diseases (Horsfall, 1955c, Tamm, 1956b). Thus, the validity of the classic principle of antimicrobial chemotherapy is in doubt so far as virus diseases are concerned.

Accordingly, there is undertaken in this chapter an analysis of the biologic and biochemical factors which determine the feasibility of various approaches, and the more meaningful results of experimental studies are presented within the framework of the biology and the biochemistry of virus infections. Because of lack of quantitative information on the relationship between virus multiplication and the development of lesions in man, and ignorance of the mechanism of viral damage, the discussion necessarily involves inferences and assumptions as well as facts.

PRINCIPLE OF ANTIMICROBIAL CHEMOTHERAPY

The fundamental principle of chemotherapy of infectious diseases caused by micro-organisms such as Chlamydozoaceae, rickettsiae, or bacteria may be stated as follows: Development of disease depends on an increase in the number of infecting pathogenic micro-organisms, if the number of micro-organisms is restricted through selective inhibition of multiplication or by selective killing of micro-organisms, disease fails to develop or is altered in favor of the host. It is implied that disease manifestations appear before the number of micro-organisms has reached maximal levels. Thus, in treatable microbial infections, symptoms and signs provide an early enough signal for initiation of chemotherapy based on the principle of restriction of the number of micro-organisms. No mention has been made of features which characterize individual microbial diseases, although it is recognized that large and important differences exist in regard to dissemination and maintenance of micro-organisms and lesions, mechanism of tissue damage, and other features. However these considerations do not affect the validity of the principle of antimicrobial chemotherapy, as defined above.

The therapeutically effective agents lack significant toxicity for the cells of the host at concentrations which are deleterious to the micro-organisms. The precise biochemical mechanism of the remarkable selective action of chemotherapeutic agents is not known.

APPLICABILITY OF THE PRINCIPLE OF ANTIMICROBIAL CHEMOTHERAPY TO VIRUS DISEASES

Whether or not the principle of antimicrobial chemotherapy is applicable to virus diseases depends on the degree of similarity between the biologic characteristics of virus diseases and the characteristics of treatable infectious diseases. This question is not concerned with the feasibility of development of highly selective virostatic or virocidal compounds but rather with the problem of whether such compounds, if found, would be useful in the treatment of virus diseases of man. The most important pertinent disease characteristic is the time relationship between multiplication of the infective agent and disease manifestations in virus diseases (Horsfall, 1955d). The information available on this point indicates that the classic principle of chemotherapy may be applicable in some but not in all virus diseases.

Interval Between Infection and Disease Manifestations

General Considerations. The feasibility of chemotherapeutic intervention directed against the infecting virus depends on the length of the interval between the first manifestations of disease and completion of those reactions which trigger the development of pathologic changes leading to the full-blown disease picture. This interval may be shorter than that between the first manifestations of disease and the time when maximal virus concentration is reached. Production of new virus particles proceeds in two steps: (1) synthesis of virus materials, and (2) assembly of new particles. It is possible that the process of synthesis of virus materials or the newly synthesized virus materials themselves can damage the host cell. In either case the infected cells may be on their way to degeneration and death before significant numbers of new virus particles have appeared in the cell. Results which have been obtained in studies on chemical inhibition of bacteriophage reproduction are of considerable interest in this connection. Chloramphenicol inhibits protein synthesis, and if added early in the latent period, it prevents both virus reproduction and host cell lysis (Bozeman et al., 1954). However, the concentration of chloramphenicol required to inhibit bacteriophage reproduction is closely similar to that which inhibits bacterial multiplication, and attempts to recover viable bacteria through drug treatment of infected bacterial cells have been unsuccessful. Proflavine interferes mainly with the final assembly of mature virus particles from precursor materials and not with the synthesis of new phage nucleic acid or protein (Foster, 1948). Although no new infective phage particles are formed in the presence of proflavine, lysis of treated bacterial cells occurs at the same time as that of untreated control cells.

The degeneration of a relatively small number of individual cells widely scattered in an

organ does not necessarily lead to manifestations of disease It is likely that a certain minimal local concentration of degenerating cells is necessary to give rise to symptoms or signs of disease Some disease manifestations clearly reflect loss of function of parenchymal cells, whereas others reflect secondary inflammatory changes in the tissues.

During the incubation period virus multiplication takes place probably both at sites of initial infection and at daughter sites It is to be expected that with different viruses infecting different tissues the time from infection to the appearance of disease manifestations would be variable because there could be differences in the rate of reproductive processes, in the rate and the manner of spread of infection, in the time when the chain of events is initiated leading to cytopathologic changes, in the rate of development of cytopathologic changes, and in the rate of development and the extent of inflammatory changes

In some diseases the virus may multiply first in one organ system, without causing detectable damage to the cells involved, and then in another, this time causing pathologic changes In such a case disease manifestations may be delayed until some time after infection of the second organ system, as in poliomyelitis (Chap 23).

Specific Diseases. In the absence of data regarding the concentration of virus materials and particles during the incubation period as well as during the various phases of disease, and regarding the precise pathogenesis and kinetics of viral lesions in man, the question as to the interval between the first manifestations of disease and those reactions which trigger the sequence of pathologic changes cannot be unequivocally answered for any of the virus infections afflicting man. Useful available information concerns the incubation period and the period of communicability (see Chapters on specific diseases and Control of Communicable Diseases in Man, 1955). These periods are known in most recognized virus diseases, the latter with much less precision than the former. Moreover, interpretation of the period of communicability for the present purposes is difficult The onset of the period of communicability probably signifies that the infecting virus had multiplied to a considerable extent. In some virus diseases the period of communicability begins before the appearance of symptoms, persons infected with the virus of yellow fever, dengue, or phlebotomus fever become infective for the appropriate vector one day before the onset of clinical disease. Poliomyelitis virus is present in the nasopharynx and the feces for several days before onset of the disease, and the infected persons may communicate the disease.

The end of the period of communicability may signify a number of different things. It may reflect primarily the termination of multiplication of the infecting virus; however, the rate of disappearance of virus probably is also of considerable importance in determining the end of the period of communicability The rate of disappearance depends on a number of factors: development of neutralizing antibodies, thermal inactivation, pH effects, possible engulfment and inactivation by macrophages, excretion and others One or another factor may be of greatest importance in a given disease. It is noteworthy that in some virus diseases such as poliomyelitis and infectious hepatitis, acute signs and symptoms of disease disappear before excretion of virus in the stools stops This does not necessarily mean that virus continues to multiply in the brain or the liver beyond the acute phase of the disease; it is more likely that the carrier state is due to multiplication of the virus in cells other than the parenchymal cells of these organs

On the basis of the limited information available, few conclusions are warranted regarding the length of the interval between infection and onset of pathologic changes irrevocably leading to full-blown lesions, i e, the interval during which selective virostatic or virocidal agents might be employed effectively. However, it does appear likely that in virus diseases of fairly long duration in which progressive involvement occurs during the course of disease not all tissues which eventually become involved may be seeded with virus at the time of onset of signs and symptoms, or the seeding may be slight. Into this group of diseases may fall mumps and possibly poliomyelitis and other diseases Primary atypical pneumonia associated with the development of cold hemagglutinins and streptococcus MG agglutinins, and infectious mononucleosis, may also fall into this category, though the virus etiology of these diseases has not been established unequivocally Although infectious or serum hepatitis is frequently of long duration, early virus lesions tend to be widespread (Dible et al., 1943; Mallory, 1947).

Thus it appears that in at least some virus infections classic chemotherapeutic approaches aiming to restrict the number of virus particles (Horsfall, 1950) are based on correct premises It is obvious, however, that success will depend on early initiation of treatment

The classic chemotherapeutic approach has been shown to be valid in the treatment of PVM virus pneumonia in mice with the capsular polysaccharide from *K pneumoniae* (Horsfall and McCarty, 1947, Ginsberg and Horsfall, 1951) When the substance is given after considerable virus multiplication has taken place and definite pneumonia has developed, further multiplication of the virus is inhibited, and the progress of the pneumonia is retarded The mice survive, and the lesions ultimately resolve

However, in considering approaches to the chemotherapy of virus diseases other avenues should also be explored, for a number of reasons (1) In certain virus diseases the duration of the whole illness is so short that classic intervention may not be practicable, and in others shortness of the interval between onset of disease manifestations and maximal involvement of tissues may preclude the effective use of virostatic or virocidal agents (2) It is frequently difficult to make a specific diagnosis very early during the course of an illness Should broad-spectrum antiviral drugs become available, this fact may not significantly decrease their usefulness However, the use of drugs with a limited antiviral spectrum in relatively mild self-limiting diseases might be impractical unless helpful epidemiologic information is available In serious diseases therapeutic trial with combinations of drugs may be justified (3) Available evidence indicates that multiplication of viral agents is so closely linked to the metabolism of host cells that it may prove to be difficult indeed to discover or develop highly selective inhibitors of virus multiplication It may be even more difficult to find ways of inactivating virus particles, particularly within host cells, without damage to cells

Ways to Implement the Classic Principle

Much work has been done both on inhibition of virus multiplication and on inactivation of virus particles However, although numerous chemical compounds and biologic substances have been reported to possess virus inhibitory activity, relatively little work has been done on the mechanism of action of such compounds, and only a few serious attempts have been made to improve the characteristics of inhibitory compounds through systematic development of new derivatives (Tamm, 1956b; 1958) In most in vitro studies the toxicity aspect has been neglected The more meaningful results which have been obtained are discussed below

Since no highly selective virostatic or virocidal agents are available at present, and since it is impossible to predict when such agents might be discovered, renewed consideration should be given to the possibility that specific antibodies given in very large doses may cause a favorable alteration in the course of some of the more serious virus diseases of man Before the advent of antimicrobial chemotherapy it was shown that certain bacterial infections, e g , pneumonococcal pneumonia (Horsfall et al , 1937), could be treated effectively with specific antibodies Admittedly, numerous reports have appeared on the failure of specific antiserum to alter the course of disease in man or in experimental animals Furthermore, the biologic features of virus infections of man suggest that even very large doses of intravenously or topically applied antibodies may possibly be effective only in a very limited number of virus infections, and only if given early in the course of illness However, a restudy of the problem, in poliomyelitis, for example, seems to be indicated, since methods are now available for obtaining gamma globulin from human beings hyperimmunized against the 3 types of poliomyelitis virus, and since early treatment should be possible in a considerable proportion of cases of this disease

Several other ways of obtaining virostatic or virocidal effects, such as with the properdin system (Ginsberg and Wedgwood, 1956), with interfering viruses or interferon (Chap 5), merit further exploration. A better understanding of factors which limit the yield of virus per cell and of those which limit the spread of virus in natural infection might open up new possibilities along the line of the classic approach

Francis (1957) has recently re-emphasized

the importance of identification of cellular components with which viruses presumably interact, in the belief that it may prove to be possible to prepare protective inhibitory analogs of such components

APPROACHES OTHER THAN THE CLASSIC

Little work has been done and few promising experimental results have been reported regarding ways to counteract the effects of viruses on cells. This is not surprising, since understanding of the processes involved in virus-host interaction is extremely limited A statement of some of the factors involved might lead to much-needed experiments in this field. Approaching the problem from the side of the virus, it would be of great interest to know whether viral damage is due to the process of virus reproduction or its products. If the first be true, the conceivable mechanisms include depletion of nutrient materials and diversion of enzyme systems, in either case the resulting reduction in the amounts of metabolites available to the host cell might be damaging per se, or it might be harmful because of an associated imbalance in the metabolic equilibrium If on the other hand virus materials are toxic (Henle and Henle, 1946a, 1946b) or cytopathogenic (Ginsberg, 1951) in themselves, then it follows that the chain of events leading to cellular degeneration could be initiated by the infecting particles, by materials released from them at the time of infection, by newly synthesized virus materials or by newly assembled virus particles, the mechanism of action might concern interruption of vital enzyme reactions in cells, disturbances in the normal cellular regulatory mechanism which maintain metabolic equilibrium, or activation of host-cell enzymes such as the nucleases and the proteinases. It should be emphasized that primary viral effects may lead to multiple secondary reactions in host cells Indeed, it is probable that in a number of virus infections the infecting virus triggers a reaction pattern of injury which may be characteristic of the particular cell type involved or may be common to different cell types.

Rivers (1928) pointed out 30 years ago that the primary pathologic changes in all virus diseases are hyperplasia, hyperplasia followed by necrosis, or necrosis. In recent years numerous reports of stimulation of various cellular metabolic activities during the early phases of virus infection have appeared (Tamm, 1958). Stimulation has been shown to be followed by depression in a number of cases (Rafelson et al, 1949; Overman and Tamm, 1957). It appears possible that at least in certain virus infections stimulation represents a metabolic disturbance which causally leads to depression of metabolic activities and degenerative changes in cell structure.

Approaching the problem of virus-host interaction from the side of the cell, it would be of great interest to know the mechanism of host resistance. Viruses may fail to infect cells or they may infect and multiply but fail to cause pathologic changes It is not known whether these phenomena are due to negative or positive factors· whether resistant cells lack constituents which the viruses require for infection or cytopathogenicity, or whether they possess inhibitory components which render the viruses inactive

There is evidence that a proportion of damaged cells in the brain and the cord of monkeys infected with poliomyelitis virus may recover (Bodian, 1949) In such nerve cells changes are arrested in the stage of cytoplasmic chromatolysis, following which complete morphologic recovery of the cell may occur over a period of about a month or less, depending on the severity of injury It is impossible to be certain whether these cells were actually infected with poliomyelitis virus or whether they showed changes which were not directly related to the presence or the multiplication of virus However, in either case, an understanding of the mechanism of recovery might open up new avenues of approach to the problem of chemotherapy of virus diseases. Also, it would be of great interest to know whether recovery of cells takes place in other virus infections. This information is not available at present. On the other hand, it is well known that in certain organs, such as the liver and the respiratory tract, repair may take place through regeneration of parenchymal cells Recently, it has been emphasized (Horsfall and Tamm, 1957; Francis, 1957) that detailed consideration of recovery phenomena in virus diseases may lead

to fruitful experiments on how to support and restore infected cells

The role of the secondary inflammatory response during both the acute and the recovery phases of virus infections has not been defined as yet It is possible that at least in certain virus diseases infiltration of leukocytes and vascular reactions may serve to limit the infection; on the other hand, inflammatory changes might cause damage in uninfected parenchymal cells or aggravate lesions in infected ones If leukocytic infiltrations and vascular changes are not useful features of the host response in certain virus infections, means might be sought to suppress such changes

EXPERIMENTAL STUDIES

Certain chemical compounds and biologic materials are sufficiently active to protect animals against death from virus infection under restricted experimental conditions (Tamm, 1956b) However, it is unlikely that any of the agents which have shown some virus inhibitory or protective activity in experimental animals would prove to be useful in the therapy or even the prophylaxis of natural virus diseases in man or animals The reasons for this are several, depending on the compound and on the virus infection In most cases the amount of compound required to produce a significant reduction in mortality has been close to the toxic dose, and treatment has had to be initiated within a short time after virus inoculation, that is, before the onset of signs of disease With few exceptions it has been possible to demonstrate protection only with relatively small virus inocula, and only in a proportion of infected animals In a number of instances the compounds employed have been effective only when given by the same route as the virus, and frequently the amounts required have been large It has often been found that treated survivors are susceptible to reinfection with the same virus

Only a small number of compounds used with some success in animals have been studied for their precise mechanism of action on the cellular level It is also true that the mechanism of action of many compounds which have been used to inhibit viruses in tissue culture is not known However, it may be said that, without exception, virus inhibitory compounds have been found to have inhibitory effects on some metabolic activity of host cells wherever such effects have been looked for (Tamm, 1958).

Studies with influenza virus have provided an indication of what can be learned about metabolic aspects of virus multiplication by the use of inhibitory compounds The most telling findings may be summarized as follows Inhibitors of biosynthetic processes have made it possible to define steps in the viral reproductive sequence. It has been established with the aid of the β-linked D-ribofuranoside of 5,6-dichlorobenzimidazole (DRB) that synthesis of ribonucleic acid (RNA) precedes the emergence of soluble complement-fixing antigen or influenza-virus particles (Tamm and Tyrrell, 1954, Tamm, 1957) Results of studies with methoxinine (Ackermann and Francis, 1954, Ackermann and Maassab, 1954) indicate that synthesis of proteins also precedes the appearance of new virus particles However, it appears that the processes concerned with influenza virus multiplication which are inhibitable by methoxinine are of longer duration than those inhibitable by the riboturanoside of dichlorobenzimidazole

Results of studies with inhibitors of energy-yielding mechanisms have imparted much meaning to the finding that influenza virus multiplication requires oxygen (Ackermann, 1951b, Tamm, 1956a) The essential function of the Krebs cycle in virus multiplication was demonstrated with the aid of malonate and fluoroacetate (Ackermann, 1951b, c), and dinitrophenol was instrumental in the demonstration of dependence of virus multiplication on availability of adenosine triphosphate (Eaton, 1952, Ackermann and Johnson, 1953, Ingraham et al, 1953)

It is possible that oxygen may be required for biosynthetic processes which take place during the latent period but not for later assembly of particles, since pentamidine (Eaton et al, 1952) and 2,5-dimethylbenzimidazole (Tamm et al, 1953, Tamm, 1956a), at concentrations inhibitory to the oxygen uptake of host tissue, reduced the yield of virus when given during the early phases of multiplication but had no effect on yield after rapid increase in new virus had begun

These results constitute a mere beginning in the understanding of the metabolic requirements of influenza virus multiplying in the chorio-allantoic membrane from embryonated

the importance of identification of cellular components with which viruses presumably interact, in the belief that it may prove to be possible to prepare protective inhibitory analogs of such components.

APPROACHES OTHER THAN THE CLASSIC

Little work has been done and few promising experimental results have been reported regarding ways to counteract the effects of viruses on cells This is not surprising, since understanding of the processes involved in virus-host interaction is extremely limited A statement of some of the factors involved might lead to much-needed experiments in this field. Approaching the problem from the side of the virus, it would be of great interest to know whether viral damage is due to the process of virus reproduction or its products. If the first be true, the conceivable mechanisms include depletion of nutrient materials and diversion of enzyme systems, in either case the resulting reduction in the amounts of metabolites available to the host cell might be damaging per se, or it might be harmful because of an associated imbalance in the metabolic equilibrium If on the other hand virus materials are toxic (Henle and Henle, 1946a; 1946b) or cytopathogenic (Ginsberg, 1951) in themselves, then it follows that the chain of events leading to cellular degeneration could be initiated by the infecting particles, by materials released from them at the time of infection, by newly synthesized virus materials or by newly assembled virus particles, the mechanism of action might concern interruption of vital enzyme reactions in cells, disturbances in the normal cellular regulatory mechanism which maintain metabolic equilibrium, or activation of host-cell enzymes such as the nucleases and the proteinases. It should be emphasized that primary viral effects may lead to multiple secondary reactions in host cells Indeed, it is probable that in a number of virus infections the infecting virus triggers a reaction pattern of injury which may be characteristic of the particular cell type involved or may be common to different cell types.

Rivers (1928) pointed out 30 years ago that the primary pathologic changes in all virus diseases are hyperplasia, hyperplasia followed by necrosis, or necrosis In recent years numerous reports of stimulation of various cellular metabolic activities during the early phases of virus infection have appeared (Tamm, 1958). Stimulation has been shown to be followed by depression in a number of cases (Rafelson et al., 1949; Overman and Tamm, 1957). It appears possible that at least in certain virus infections stimulation represents a metabolic disturbance which causally leads to depression of metabolic activities and degenerative changes in cell structure

Approaching the problem of virus-host interaction from the side of the cell, it would be of great interest to know the mechanism of host resistance. Viruses may fail to infect cells or they may infect and multiply but fail to cause pathologic changes It is not known whether these phenomena are due to negative or positive factors whether resistant cells lack constituents which the viruses require for infection or cytopathogenicity, or whether they possess inhibitory components which render the viruses inactive

There is evidence that a proportion of damaged cells in the brain and the cord of monkeys infected with poliomyelitis virus may recover (Bodian, 1949). In such nerve cells changes are arrested in the stage of cytoplasmic chromatolysis, following which complete morphologic recovery of the cell may occur over a period of about a month or less, depending on the severity of injury It is impossible to be certain whether these cells were actually infected with poliomyelitis virus or whether they showed changes which were not directly related to the presence or the multiplication of virus However, in either case, an understanding of the mechanism of recovery might open up new avenues of approach to the problem of chemotherapy of virus diseases. Also, it would be of great interest to know whether recovery of cells takes place in other virus infections. This information is not available at present On the other hand, it is well known that in certain organs, such as the liver and the respiratory tract, repair may take place through regeneration of parenchymal cells. Recently, it has been emphasized (Horsfall and Tamm, 1957; Francis, 1957) that detailed consideration of recovery phenomena in virus diseases may lead

acid or protein synthesis might have a greater effect with more significant consequences on the synthesis of virus than host-cell material

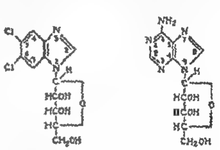
However, Horsfall (1950) cautioned earlier that, if the rate of turnover of cellular proteins and nucleic acids must be generally reduced to inhibit viral synthesis, it becomes highly improbable that attempts to discover effective chemotherapeutic agents active against viral infections will be fruitful, because substances which diminish either protein or nucleic acid synthesis within the cell would be directed against what are in all probability some of the most vital systems in cell biochemistry and could be expected to exert damaging effects on the host Indeed, if it proves to be true that no significant quantitative differences exist rendering the process of virus synthesis relatively more susceptible to the effects of some potent inhibitor, presently feasible studies on inhibition of nucleic acid or protein synthesis may not lead to the discovery of highly selective inhibitors of virus multiplication In any event, it is essential to proceed slowly and with caution and to explore the potentialities of new compounds widely in experimental animals before attempting to treat patients with them (Horsfall, 1954)

The experimental work reviewed below has been arranged according to mechanism of action of inhibitory compounds However, it should be emphasized, that very little direct and conclusive evidence is available deriving from studies under conditions of virus inhibition experiments

Experiments Aimed at Inhibition of Nucleic Acid Synthesis

Influenza and Mumps Viruses. Extensive investigations on the relationship between chemical structure of benzimidazole derivatives and their virus inhibitory activity have led to the synthesis of new compounds of very high activity (Tamm, 1956b, 1958) Less than 1 μg/ml of the β-D-ribofuranoside of monobromo-dichlorobenzimidazole causes marked inhibition of influenza B virus multiplication in the chorio-allantoic membrane from the embryonated chicken egg in vitro (Tamm, Folkers and Shunk, 1956), this compound is the most active inhibitor of virus multiplication reported

The structure of the β-D-ribofuranoside of dichlorobenzimidazole (DRB) (Tamm et al., 1954), a congener of the compound referred to above, and the time of its action early in the latent period of the reproductive cycle (Tamm and Tyrrell, 1954) suggested that β-linked ribofuranosides of halogenated benzimidazoles act through inhibition of RNA synthesis (Tamm, 1956b) This conclusion was borne out in experiments on inhibition by DRB of incorporation of adenosine-8-C^{14} into RNA of the host tissue (Tamm, 1957) and of orotic acid-6-C^{14} into RNA of isolated calf thymus nuclei (Allfrey et al, 1957) The diagram depicts the structural relationship between 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB) and 9-β-D-ribofuranosyladenine (adenosine) The latter



5,6-Dichloro-1-β-D-ribofuranosylbenzimidazole (Inhibitor) | 9-β-D-Ribofuranosyladenine (In RNA)

Comparison of the structures of 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB) and 9-β-D-ribofuranosyladenine (adenosine)

is a natural metabolite present in RNA, adenosine mono-, di- and triphosphate and in several coenzymes Adenosine is capable of blocking the inhibitory action of DRB if low concentrations of the inhibitor are employed (Tamm, 1957) The combined evidence suggests that the β-linked ribofuranosides of halogenated benzimidazoles act as highly effective metabolic antagonists of a natural purine riboside

High inhibitory activity against the RNA-containing (Ada and Perry, 1954) influenza virus depends on two structural features: (1) the presence of the D-ribofuranose moiety in β-linkage at N1 in the imidazole ring, and (2)

chicken eggs in vitro Less is known about the requirements of other viruses.

No attempt will be made to review in detail the results of the numerous studies which bear on the problem of chemotherapy of virus infections Numerous recent reviews of work in this field are available (Horsfall, 1950, 1954, 1955a, b, c; Matthews and Smith, 1955, Hurst and Hull, 1956; Tamm, 1956b, 1958; Horsfall and Tamm, 1957, Francis, 1957). Instead, the more significant findings are discussed in terms of the varied mechanisms of action of the compounds and the substances used Work dealing with inhibition of viral multiplication or direct inactivation of the infective property of virus particles is discussed first. In later sections results bearing on other feasible approaches are summarized

Compounds and substances were chosen for review on a number of bases (1) because they provided examples illustrating certain modes of action, (2) because the accumulated evidence indicates that structural modification of presently available compounds might yield more effective compounds, (3) because protection against death was demonstrated in animal experiments, (4) because a synergistic effect was demonstrated, or (5) because the compounds used were highly active on a weight basis An attempt has been made to illustrate principles and concepts with the most complete examples available.

SELECTIVE INHIBITION OF VIRUS MULTIPLICATION

Present evidence indicates that the process of virus reproduction is dependent on host cells not only for building blocks such as nucleotides and amino acids but also for energy, and probably even for enzyme systems which may be required in the synthesis of virus materials. The intimacy of the host-virus relationship is strikingly reflected in the fact that synthesis of some virus materials appears to take place in the temporary absence of a limiting virus membrane (Morgan et al, 1954a, b; Hershey and Melechen, 1957). In view of these circumstances it is not surprising that highly selective inhibitors of virus multiplication have not yet been discovered or that their development is proving to be difficult.

A search for ways to inhibit synthesis of virus materials without inhibiting synthesis of corresponding host materials leads to the consideration of the chemical basis of the specificity of viruses. At the present time little information is available about the chemical basis of the heritable biologic specificity exhibited by viruses beyond the knowledge that nucleic acids and possibly proteins are involved. The relatively small number of different building blocks in virus nucleic acids and proteins and their common occurrence in biologic materials from many sources suggest that the sequence of nucleotides in nucleic acids and of amino acids in proteins may form the chemical basis for the biologic specificity of these chain molecules The discovery that in the deoxyribonucleic acid (DNA) from bacteriophages T2, T4 and T6 hydroxymethylcytosine replaces cytosine or its 5-methyl derivative (Wyatt and Cohen, 1953) has not led thus far to the finding of this base in other viruses or to the discovery of other virus specific bases There are indications that with proteins the shape of the molecule may also be important in determining biologic specificity

If the sequence of the repeating units were known it might be possible to design inhibitors which would interfere with the process of assembly of virus materials without interfering with the synthesis of host materials of a similar kind Because of limitations in knowledge, it is impossible to analyze the practicability of such an approach or to plan its execution at the present time However, it should be strongly emphasized that the chemistry of biosynthesis of nucleic acids and of proteins is in its infancy and that much progress may be expected within the next decade Also, empirical discovery of new inhibitors of these biosynthetic processes may greatly facilitate study of the steps and the intermediates involved.

As an alternative approach it has been suggested (Tamm, 1956b, 1958) that it may be more profitable to attempt exploitation of probable quantitative differences in the biosynthetic demands of the virus vs the host cell If considerable quantitative difference existed with respect to the conditions and the requirements of virus vs host material synthesis, an inhibitor of some step in nucleic

of dichlorobenzimidazole, namely, the α-linked D-arabinopyranoside did show enhanced selectivity with poliomyelitis virus. Although both compounds inhibited RNA synthesis at concentrations inhibitory for the poliomyelitis virus, surprisingly the arabinopyranoside also had a marked effect on protein synthesis (Nemes and Tamm, 1958). Thus, a high degree of inhibition of protein synthesis is not necessarily associated with a marked cytotoxic effect, and, furthermore, cytotoxicity and virus inhibitory activity do not necessarily go hand in hand

The biochemical action of DRB as an inhibitor of RNA synthesis was correlated with the kinetic finding that the greater part of its effect on poliomyelitis virus multiplication took place early during the latent period In contrast, the arabinopyranoside caused marked inhibition of protein synthesis, and with it inhibition of virus multiplication was obtained throughout the latent period and even beyond

Further support for the tentative conclusion that inhibition of protein synthesis provided an approach to the selective inhibition of poliomyelitis virus multiplication which was preferable to inhibition of RNA synthesis was obtained in experiments with azaserine and p-fluorophenylalanine Azaserine, which may be considered an inhibitor of RNA synthesis (Buchanan et al, 1957; Goldthwait, 1957), was considerably less selective as an inhibitor of poliomyelitis virus multiplication than p-fluorophenylalanine, which is probably an inhibitor of protein synthesis (Halvorson and Spiegelman, 1952)

Brown (1952) was the first to show that unsubstituted benzimidazole inhibited poliomyelitis virus in tissue culture A mixture of adenine, guanine and uracil partially blocked the inhibitory effect of benzimidazole This compound caused only a slight reduction in mortality of mice infected with the Lansing strain of poliomyelitis type II virus (Brown et al, 1953). Lack of a more marked effect is not surprising, since benzimidazole is an inhibitor of low activity, and since it has been demonstrated that at concentrations inhibitory to the multiplication of the Mahoney strain of poliomyelitis type I virus it causes a reduction in the oxygen uptake of HeLa cells (Gifford et al, 1954).

Experiments Aimed at Inhibition of Protein Synthesis

There are numerous reports in the literature on the inhibitory effect of amino acid analogs on the multiplication of influenza and poliomyelitis viruses, and on blocking of inhibition by appropriate amino acids The amino acid analogs which have been used include, among others, DL-methoxinine (Ackermann, 1951a), DL-ethionine (Ackermann, 1951a, Brown and Ackermann, 1951), p-fluorophenylalanine (Ackermann et al., 1954), L-canavanine (Pilcher et al, 1955), and threo-β-phenylserine (Dickinson and Thompson, 1957)

Where the amino acid analogs were examined for possible protective effect in animals, no evidence of protection could be found Two factors seem to be pertinent (1) low virus inhibitory activity of amino acid analogs, and (2) easy blocking of inhibition by the appropriate amino acid

It is hoped that some entirely new ways of inhibiting protein synthesis will be discovered

Inhibition of Energy-Yielding Mechanisms

Sodium monofluoroacetate, an inhibitor of citric acid oxidation, caused some inhibition of influenza A virus multiplication in the mouse lung (Ackermann, 1951c; Mogabgab and Horsfall, 1952) In mice infected with poliomyelitis type II virus sodium monofluoroacetate caused some suppression of virus multiplication and delayed slightly the onset of illness (Ainslie, 1952) In monkeys infected with poliomyelitis type I virus this compound caused a reduction in the number of animals developing paralysis but had no effect on the length of the incubation period (Francis et al, 1954)

Influenza virus multiplication in the embryonated egg was inhibited by 2,4-dinitrophenol and by sodium azide (Hannoun, 1954) The first compound acted presumably through interference with oxidative phosphorylation and the second through interference with oxidative processes

It seems doubtful that inhibition of energy-yielding processes will provide an approach to highly selective inhibition of virus multiplication

the presence of multiple halogen substituents in the benzenoid ring (Tamm, 1956b).

The selectivity of action of DRB was assessed in experiments in which the effects of this compound on a number of metabolic processes of the host tissue were determined at virus inhibitory concentrations. In addition, the effects of DRB on morphologic features of the tissue and the ability of cells to proliferate were also studied. In the presence of DRB at a concentration causing 75 per cent reduction in the yield of virus, moderate reduction in the uptake of adenosine-8-C^{14} into RNA of the uninfected chorio-allantoic membrane was observed (Tamm, 1957) At this concentration incorporation of C^{14}-L-alanine into the protein fraction and oxygen uptake of the tissue were not affected, and by microscopic examination large areas of the membrane showed no evidence of damage (Tamm, 1957, 1956a) At double this concentration of DRB, oxygen uptake was still not affected, but cells of the membrane grew out from explants at a reduced rate in roller-tube cultures (Tamm et al, 1954) On removal of the compound, cells proliferated rapidly, and the monolayer of cells surrounding the explant reached the size which had been attained earlier by the control cultures At a concentration 5 times greater than the 75 per cent virus inhibitory concentration microscopic examination showed considerable evidence of damage At even higher concentrations, microscopic damage was marked, oxygen uptake was reduced, and the membranes appeared grossly abnormal

Results of experiments in intact animals support the conclusion suggested by the in vitro findings, namely, that DRB shows some selectivity in its inhibitory action on influenza virus multiplication DRB inhibits influenza B and mumps virus multiplication in the embryonated egg, and influenza B virus multiplication in the mouse lung under restricted experimental conditions (Tamm, 1954; Tamm et al, 1954). This compound is capable of prolonging slightly the survival time of infected mice when administration is started 2 hours after inoculation of virus (Tamm, 1956c). However, DRB is not selective enough to be used in sufficient amounts to cause inhibition for a period of more than a few days without damage to the host

A comparison of DRB with 2,5-dimethylbenzimidazole, a derivative which was studied earlier (Tamm et al., 1952), is illuminating (Tamm, 1956a). Not only is DRB much more active as an inhibitor of virus multiplication than the 2,5-dimethyl compound, but it is also more selective as determined in experiments on: (1) inhibition of oxygen uptake by membranes; (2) cytotoxicity in membranes; (3) inhibition of proliferation of host cells, and (4) toxicity for chicken embryos and mice.

Thus, virus inhibitory activity and toxicity of compounds may vary independently, certain modifications in the structure of the inhibitor molecule have resulted in a disproportionate increase in virus inhibitory activity relative to toxicity, i e, in more selective derivatives Instances have also been observed where alteration of the molecular structure reduced toxicity without affecting virus inhibitory activity.

It appears that possibilities for increasing further the virus inhibitory effectiveness of benzimidazole derivatives through modifications in structure have not yet been exhausted

Poliomyelitis Virus. The structure-activity relationships established with a series of glycosides of chlorinated benzimidazoles and poliomyelitis type II virus in monkey kidney cells in vitro (Tamm and Nemes, 1957) paralleled those determined with influenza B virus (Tamm, 1956b) This is not surprising, since the nucleic acid in poliomyelitis virus is also of the RNA type (Schwerdt and Schaffer, 1955) However, it is noteworthy that quantitatively poliomyelitis virus was less susceptible to inhibition by the β-linked ribofuranoside of 5,6-dichlorobenzimidazole (DRB) than influenza virus The explanation for this difference probably concerns intracellular conditions of synthesis of virus materials and may involve factors such as quantitative differences in the metabolic requirements of these viruses, differences in the location of sites of synthesis of virus materials, differences in the effects of these viruses on the metabolism of host cells, or other features characteristic of each virus.

At the higher concentration required to inhibit poliomyelitis virus DRB caused microscopic damage to host cells (Tamm and Nemes, 1957). Another, less active glycoside

the Mahoney strain of poliomyelitis type I virus were protected against death by intravenous injection of very large amounts of specific antibodies, even though the administration of antibodies was delayed 48 hours. In the treated groups the incidence of paralysis was almost as high as that in control groups, but its degree was much less severe, and it involved only the lower extremities.

General Remarks. Since specific antibodies provide an excellent method of direct inactivation of virus particles in the blood or tissue fluids, any compound or component would have to be superior to antibodies in its protective action to gain justified attention. Clearly, compounds capable of selectively inactivating virus precursor materials or particles inside host cells would be of great interest.

VARIOUS OTHER MECHANISMS

Interference with Adsorption, Penetration, or Release of Virus Particles. Pretreatment of embryonated eggs with *Vibrio cholerae* filtrate, containing the so-called receptor-destroying enzyme (RDE), reduced the susceptibility of chick embryos to influenza virus (Stone, 1948a). Similar results were obtained in the mouse (Stone, 1948b). It is probable that RDE removed from the cell surface attachment sites necessary for adsorption of virus particles to host cells. Ackermann and Maassab (1954) have presented evidence that α-amino-*p*-methoxyphenylmethanesulfonic acid interferes with the penetration and the release of influenza virus from host cells.

Modification of Tissue Lesions. Xerosin, a biologic product prepared from culture filtrates of *Achromobacter xerosis*, suppressed the development of pneumonia in mice infected with influenza or Newcastle disease virus (Groupé et al., 1952, 1953). It should be emphasized that xerosin is neither virostatic nor virocidal, its effects appear to be mediated through the mechanisms of host response to injury. Indeed, xerosin appears to be primarily an anti-inflammatory agent (Ginsberg, 1955).

Newcastle disease virus does not multiply in the mouse lung but causes marked pneumonia and kills mice when given in sufficient quantities (Ginsberg, 1951). Xerosin protected mice against death from Newcastle disease virus pneumonia but caused only a delay in death when mice were infected with influenza virus. It appears that this substance has little if any effect on the primary damaging action of influenza virus on the epithelial cells lining the bronchi and the bronchioles but that it is capable of inhibiting secondary reactions such as edema, hemorrhage and infiltration (Ginsberg, 1955).

Nutritional, Hormonal and Environmental Factors. Hurst and Hull (1956) have emphasized that an animal weak or sickly from any cause may not respond typically to a virus infection. Thus, modified infection in animals whose state of health has been impaired by administration of toxic doses of a chemical substance, deficient diet, abnormal environmental conditions or by other circumstances, should not be accepted as evidence of successful chemotherapy.

Increased or decreased susceptibility may follow a wide variety of procedures which have no direct relevance to current concepts of chemotherapy but may provide information of value from the viewpoint of development of new approaches.

The fairly numerous reports in this area have been summarized by Hurst and Hull (1956).

MECHANISM UNKNOWN

It is important to point out that empirical testing of synthetic compounds and biologic materials has yielded agents capable of preventing death of animals from virus infections under restricted experimental conditions. For example, among synthetic compounds thiosemicarbazones protect mice against vaccinia virus (Hamre et al., 1951, Thompson et al., 1953), and quinacrine protects against Eastern equine encephalomyelitis virus (Hurst et al., 1952). Among biologic materials MS-8450, a culture filtrate from *Penicillium stoloniferum* (Powell and Culbertson, 1953), and helenine, an acetone precipitate of an extract obtained from the culture pellicle of *Penicillium funiculosum* (Shope, 1953), have shown protective activity against poliomyelitis virus in the monkey (Cochran et al., 1954, Cochran and Francis, 1956).

Pretreatment of monkey testicular cells in vitro with MS-8450 prevented the cyto-

Biochemical Mechanism Unknown

As was indicated above, the capsular polysaccharide from *K. pneumoniae* which inhibits the multiplication of pneumonia virus of mice (PVM) also shows chemotherapeutic activity (Horsfall and McCarty, 1947, Ginsberg and Horsfall, 1951) In addition, the polysaccharide is a highly active inhibitor of mumps virus multiplication in the embryonated egg (Ginsberg et al., 1948).

Certain acridines (Eaton et al, 1951). and pentamidine and stilbamidine (Eaton et al., 1952) are highly active inhibitors of influenza and mumps virus multiplication in tissue culture At virus inhibitory concentrations these compounds inhibited outgrowth of fibroblasts from tissue explants, the acridines had no effect on oxygen uptake or glycolysis, whereas pentamidine inhibited respiration

General Remarks

It should be emphasized that in all of the studies referred to the compounds employed did not inactivate the infective property of virus particles. The effects observed probably were due to reduction in the rate of virus reproduction

As far as is known, viruses do not possess energy-yielding mechanisms of their own Therefore, interference with energy-yielding mechanisms reduces the yield of virus wholly through effects on host-cell metabolism Compounds currently employed to inhibit nucleic acid or protein synthesis probably interfere with the synthesis or the utilization of low-molecular intermediates or precursors common for host and virus materials It is likely that reactions on this level are catalyzed by host-cell enzymes Thus, it is possible that all present-day inhibitors of biosynthetic processes reduce the yield of virus through inhibition of host-cell processes.

DIRECT INACTIVATION OF VIRUS PARTICLES

Chemical Compounds. Embryonated eggs were protected against death from Newcastle disease virus infection by treatment with small amounts of β-ethoxy-α-ketobutyraldehyde hydrate (Kethoxal). This and related compounds possess virocidal activity against Newcastle disease and certain other viruses (McLimans et al., 1957). It is likely that protection of a lesser degree, demonstrated with polylysine, is also due to a direct effect on virus particles (Green et al, 1953).

It should be pointed out that no compounds have been reported to be capable of selectively inactivating virus particles or virus components inside host cells

Cell or Tissue Components. Specific inhibition of the lytic action of bacteriophage by bacterial extracts was first demonstrated by Levine and Frisch (1934). The active principle appeared to be carbohydrate in nature Subsequently, it was shown that the specific lipocarbohydrate of Phase II *Sh sonnei* inactivates T4 bacteriophage and causes release of the content of the viral membrane into the surrounding medium (Jesaitis and Goebel, 1955)

A mucopolysaccharide isolated from the intestinal tissue of the mouse specifically combines with the GDVII strain of Theiler's encephalomyelitis virus of mice (Mandel and Racker, 1953a, b). In the combined state the virus fails to infect host cells or to agglutinate red cells The reaction between the mucopolysaccharide and the virus requires the presence of electrolyte, and the complex can be readily dissociated by decreasing the electrolyte concentration (Mandel, 1957).

The specific mucoprotein substrate of influenza virus enzyme reduces the infectivity of influenza virus as tested by allantoic injection into embryonated eggs (Tamm and Horsfall, 1952). The conclusion suggests itself that in the combined state the virus is unable to infect allantoic cells Since the virus is capable of enzymatically freeing itself from combination with the mucoprotein, the effect of the mucoprotein on infectivity is probably indirect and presumably is due to thermal inactivation, in the allantoic cavity, of the infective property of temporarily combined virus It is of considerable interest that periodate-treated mucoprotein, while capable of combining with influenza virus, is insusceptible to its enzymatic action. This modified substrate also causes a reduction in the infectivity of influenza virus for embryonated eggs (Burnet, 1948).

Antibodies. Macnamara and Morgan (1932) reported that human immune serum in the amount of 50 ml given in part intrathecally and in part intravenously reduced the extent of paralysis and the mortality in man from poliomyelitis if administered during the preparalytic stage but not when it was given after onset of paralysis. Recently, Liu et al. (1957) found that rhesus monkeys infected intraspinally in the lumbar region with

pathogenic effect of poliomyelitis virus (Hull and Lavelle, 1953) It is not established whether this unique result was due to prevention of infection, inhibition of virus multiplication, alteration of host cell response, or to some other mechanism

Exploration of the mechanism of action of the various agents may lead to new insights into the biology and the biochemistry of virus infections

SYNERGISM

Combined treatment of mice infected with Columbia SK encephalomyelitis virus with helenine and specific immune serum afforded a considerably greater degree of protection against death than treatment with either agent alone (Shope, 1953). Similar results were obtained with levo-γ-(o-chlorobenzyl)-δ-oxo-γ-phenyl caproic acid (caprochlorone) and human gamma globulin in mice infected with influenza virus (Liu et al, 1957).

The combined protective effect of isatin thiosemicarbazone and 5-(2′ 4′-dichlorophenoxy)thiouracil against vaccinia infection in mice was much greater than the effect of either compound given separately (Bauer, 1955)

CONCLUSIONS

Many different approaches to the problem of chemotherapy of virus diseases appear to be feasible. Among the most promising, currently practicable lines of approach are the following (1) development of highly selective inhibitors of virus multiplication, (2) exploration of the efficacy of large amounts of specific homologous antibodies; (3) determination of the mechanism and the role of inflammatory changes in virus infections

In view of the inherent limitations of any single approach it appears advisable to combine, whenever feasible, several approaches; a relatively small effect obtainable with a single procedure may be magnified when several methods of treatment are applied together.

The importance of fundamental investigations in the biology and the biochemistry of virus infections should not require emphasis. In a number of areas not enough is known even to formulate effective working hypotheses Susceptibility or resistance of cells to infection, viral cytopathogenicity, the nature and the mechanism of degenerative changes in cells, limiting factors which determine amount of virus produced, and recovery processes are some of the aspects of virus-host interaction, which, if understood, might lead to new approaches to chemotherapy of virus infections.

Bacteriophages

INTRODUCTION

Owing to the rapidly increasing scope of the subject in recent years, a chapter on bacteriophages can only sketch an outline of present knowledge Some historical notes will serve to add perspective

D'Herelle (1917, 1926) discovered bacteriophages and worked out the lytic cycle of their growth in general terms. attachment of phage particle to bacterium, penetration within, intracellular multiplication of phage, and cellular lysis liberating new phage particles He regarded the phages as members of a single species of parasitic ultramicrobe, but it is doubtful whether he should be given additional credit for this view, which was incorrect in important respects However, his main line of research is being pursued to this day in the direction he gave it

Other workers, notably Andrewes, Asheshov, Burnet and Elford collected evidence concerning the biologic structure of phage populations which, together with d'Herelle's analysis of phage growth, constitutes the main justification for calling phages bacterial viruses. Burnet's (1934) statement of this view makes excellent reading today Burnet concluded that the phages are represented by many species differing in many of the ways, including correlated differences, by which organisms of all kinds are classified. Thus a given phage particle is a member of a population of similar particles sharing a common inheritance but separated once and for all from other populations of very different particles, each dissimilar type forming its own community. Among such communities one can recognize types, subtypes and larger classes, however difficult it may be to define the several categories

Phage research up to 1950, though marked by many surprising discoveries, served only to strengthen the lines of thought summarized above The diverse and complex morphology of phages observed with the electronic microscope confirmed the idea of species differentiation (Luria and Anderson, 1942) Genetic variation and genetic recombination provided additional means of defining phage communities and helped to give phages their proper place in the hierarchy of organisms (Hershey, 1946) Chemical (Hook et al., 1946), metabolic (Cohen, 1949; Putnam and Kozloff, 1950), radiobiologic (Luria and Latarjet, 1947; Luria, 1947) and genetic (Hershey and Rotman, 1949) studies re-emphasized the obligatory intracellular character of phage growth and set the future course of phage research.

The decade of the forties was unique not only as a period of rapid discovery but also because of technical developments that made and continue to make discovery possible Parallel technics of revolutionary character were introduced into the seemingly unrelated fields of phage research and bacterial genetics, but these fields were not to remain separated for long. Though it is difficult to name inventors without going far afield into history,

no one will question the lasting importance to phage research of the one-step growth experiment of Ellis and Delbruck (1939), the analysis of bacterial mutation by Luria and Delbruck (1943) and of phage mutation by Luria (1945), and the broad development of bacterial genetics proceeding from the work of Lederberg and Tatum (1946)

The summary given above does not exhaust early phage history Bordet, Bail, and others had described lysogenic bacteria, albeit in confusing terms suggesting, to d'Herelle's adherents, spontaneous generation of phages. Burnet and McKie (1929) understood lysogeny with particular clarity and in a manner that could resolve the apparent conflict between this phenomenon and lytic infection However, no public agreement concerning lysogeny was reached until many new experimental technics were brought to bear beginning about 1950, with dramatic consequences

Two developments, in fact, beginning about this same time, were to alter radically earlier notions about phages At the same time or even before, similar revolutions were taking place in the study of animal and plant viruses For phages these developments begin with the work of Doermann and Dissosway (1949, see Doermann, 1953) showing that phages multiply in noninfective form inside bacteria they are going to lyse, and with remarkably fruitful inquiries into the fundamental nature of lysogeny, by Lwoff and Gutmann (1950), Bertani (1951) and the Lederbergs (1953) The work with lysogenic bacteria also showed that phages could multiply in noninfective form and, moreover, could make lasting peace with their bacterial hosts Anyone interested in early history may read, besides the papers cited, general discussions by Luria (1950) and Hershey (1952), which happen to have been written at a critical time, and the comprehensive review by Lwoff (1953), written when some of the main issues were being settled

For the remainder of this chapter we ignore past history and focus directly on current research, in which the discerning reader will detect a bias. The nature of this bias should perhaps be stated at the outset

Phages are now known to contain a functional equivalent to the chromosomes of other organisms Rightly or wrongly, it is believed that a phage chromosome is a single molecule of deoxyribonucleic acid, structurally very different from the chromosomes of other organisms Therefore, one major aim of phage research is to relate viral inheritance and function to nucleic acid structure and function; to create, in a word, a science of molecular genetics The gains for medical biology from this pursuit are scarcely predictable.

Phages also play subtle and complex roles in bacterial inheritance and function Elucidation of this aspect of phage biology is revealing new modes of variation in the potentialities of cells and should help to define the place of viruses in cellular economy, pathologic and otherwise The importance of this goal to medical and biologic problems has been recognized for a long time

The bias mentioned above consists of conscious cleaving to the stated goals, which are ambitious ones. Present results suggest that failure to reach them will not prove to be unrewarding If so, the bias is harmless

Finally, it should be made clear that the phages represent a moderately homogeneous class of highly specialized viruses, adapted to cohabitation with bacteria For one thing, they all seem to contain deoxyribonucleic acid as a major component, which is true of few or no animal viruses It would be naive, to say the least, to look to the bacteriophages for direct clues to the pathogenesis of specific viral diseases of man

For further information about phages the reader is referred to the frequent current reviews and to a complete text, the first in 30 years, in press at the time of the present writing (Adams, 1958).

THE GROWTH CYCLE

The general character of bacteriophages is best conveyed by a brief description of the cycle of their growth Extracellular phage particles are inert objects often called *mature* or *resting* particles They are found wherever bacteria occur They first show signs of life when they encounter a specifically receptive host bacterium Following attachment to the cell, the phage particle literally splits into two parts of roughly equal mass, one composed chiefly of deoxyribonucleic acid (DNA) that penetrates inside the bacterium, the other composed chiefly of protein that does not

Bacteriophages

INTRODUCTION

Owing to the rapidly increasing scope of the subject in recent years, a chapter on bacteriophages can only sketch an outline of present knowledge Some historical notes will serve to add perspective.

D'Herelle (1917, 1926) discovered bacteriophages and worked out the lytic cycle of their growth in general terms· attachment of phage particle to bacterium, penetration within, intracellular multiplication of phage, and cellular lysis liberating new phage particles He regarded the phages as members of a single species of parasitic ultramicrobe, but it is doubtful whether he should be given additional credit for this view, which was incorrect in important respects However, his main line of research is being pursued to this day in the direction he gave it

Other workers, notably Andrewes, Asheshov, Burnet and Elford collected evidence concerning the biologic structure of phage populations which, together with d'Herelle's analysis of phage growth, constitutes the main justification for calling phages bacterial viruses. Burnet's (1934) statement of this view makes excellent reading today. Burnet concluded that the phages are represented by many species differing in many of the ways, including correlated differences, by which organisms of all kinds are classified Thus a given phage particle is a member of a population of similar particles sharing a common inheritance but separated once and for all from other populations of very different particles, each dissimilar type forming its own community Among such communities one can recognize types, subtypes and larger classes, however difficult it may be to define the several categories

Phage research up to 1950, though marked by many surprising discoveries, served only to strengthen the lines of thought summarized above The diverse and complex morphology of phages observed with the electronic microscope confirmed the idea of species differentiation (Luria and Anderson, 1942) Genetic variation and genetic recombination provided additional means of defining phage communities and helped to give phages their proper place in the hierarchy of organisms (Hershey, 1946). Chemical (Hook et al., 1946), metabolic (Cohen, 1949, Putnam and Kozloff, 1950), radiobiologic (Luria and Latarjet, 1947, Luria, 1947) and genetic (Hershey and Rotman, 1949) studies re-emphasized the obligatory intracellular character of phage growth and set the future course of phage research.

The decade of the forties was unique not only as a period of rapid discovery but also because of technical developments that made and continue to make discovery possible. Parallel technics of revolutionary character were introduced into the seemingly unrelated fields of phage research and bacterial genetics, but these fields were not to remain separated for long. Though it is difficult to name inventors without going far afield into history,

no one will question the lasting importance to phage research of the one-step growth experiment of Ellis and Delbrück (1939), the analysis of bacterial mutation by Luria and Delbruck (1943) and of phage mutation by Luria (1945), and the broad development of bacterial genetics proceeding from the work of Lederberg and Tatum (1946)

The summary given above does not exhaust early phage history Bordet, Bail, and others had described lysogenic bacteria, albeit in confusing terms suggesting, to d'Herelle's adherents, spontaneous generation of phages Burnet and McKie (1929) understood lysogeny with particular clarity and in a manner that could resolve the apparent conflict between this phenomenon and lytic infection However, no public agreement concerning lysogeny was reached until many new experimental technics were brought to bear beginning about 1950, with dramatic consequences.

Two developments, in fact, beginning about this same time, were to alter radically earlier notions about phages At the same time or even before, similar revolutions were taking place in the study of animal and plant viruses For phages these developments begin with the work of Doermann and Dissosway (1949, see Doermann, 1953) showing that phages multiply in noninfective form inside bacteria they are going to lyse, and with remarkably fruitful inquiries into the fundamental nature of lysogeny, by Lwoff and Gutmann (1950), Bertani (1951) and the Lederbergs (1953) The work with lysogenic bacteria also showed that phages could multiply in noninfective form and, moreover, could make lasting peace with their bacterial hosts. Anyone interested in early history may read, besides the papers [illegible]

sive review by Lwoff (1953), written when some of the main issues were being settled.

For the remainder of this chapter we ignore past history and focus directly on current research, in which the discerning reader will detect a bias. The nature of this bias should perhaps be stated at the outset.

Phages are now known to contain a functional equivalent to the chromosomes of other organisms Rightly or wrongly, it is believed that a phage chromosome is a single molecule of deoxyribonucleic acid, structurally very different from the chromosomes of other organisms Therefore, one major aim of phage research is to relate viral inheritance and function to nucleic acid structure and function; to create, in a word, a science of molecular genetics. The gains for medical biology from this pursuit are scarcely predictable.

Phages also play subtle and complex roles in bacterial inheritance and function. Elucidation of this aspect of phage biology is revealing new modes of variation in the potentialities of cells and should help to define the place of viruses in cellular economy, pathologic and otherwise The importance of this goal to medical and biologic problems has been recognized for a long time

The bias mentioned above consists of conscious cleaving to the stated goals, which are ambitious ones Present results suggest that failure to reach them will not prove to be unrewarding If so, the bias is harmless

Finally, it should be made clear that the phages represent a moderately homogeneous class of highly specialized viruses, adapted to cohabitation with bacteria For one thing, they all seem to contain deoxyribonucleic acid as a major component, which is true of few or no animal viruses It would be naive, to say the least, to look to the bacteriophages for direct clues to the pathogenesis of specific viral diseases of man

For further information about phages the reader is referred to the frequent current reviews and to a complete text, the first in 30 years, in press at the time of the present writing (Adams, 1958)

THE GROWTH CYCLE

The general character of bacteriophages is best conveyed by a brief description of the cycle of their growth Extracellular phage particles are inert objects often called *mature* or *resting* particles They are found wherever bacteria occur. They first show signs of life when they encounter a specifically receptive host bacterium Following attachment to the cell, the phage particle literally splits into two parts of roughly equal mass, one composed chiefly of deoxyribonucleic acid (DNA) that penetrates inside the bacterium, the other composed chiefly of protein that does not

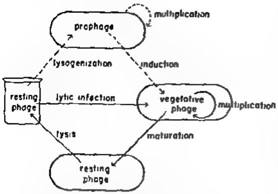

FIG 43. The life cycle of bacteriophages All stages are intrabacterial except the one represented in a beaker. The broken lines indicate processes forbidden to virulent phages (Hershey, A D, 1957, Bacteriophages as genetic and biochemical systems *in* Advances in Virus Research, *4*:25-61, New York, Acad Press)

penetrate This manner of penetration, often called *injection*, accounts for one of the main characteristics of the growth cycle, when mature phage particles are formed in an infected cell they are new particles, arising in a bacterium that previously contained nothing similar to them.

Infection of the appropriate host bacterium with a phage particle typically leads to the production of many offspring particles that can escape from the bacterium only when it lyses, which it commonly does some minutes after infection This sequence of events is called the *lytic cycle* of phage growth

The infection can proceed in a very different manner from that described above Usually rarely, but in some systems very frequently, the infected cell survives and multiplies to yield infected daughter cells. These infected cells do not often produce mature phage particles or lyse during continued growth However, an occasional daughter cell may do so, and the infection is recognized mainly by this tendency A pure culture of such viable infected cells is called a *lysogenic* culture, the infection giving rise to it is called *lysogenization*, and the occasional lapse of a lysogenic bacterium into the lytic cycle of phage growth is called *spontaneous phage production* or, especially when brought about by experimental means, *induction*. The lytic cycle following induction and the lytic cycle following primary infection are identical.

All naturally occurring phages can initiate the lytic cycle of growth, which is necessary for their perpetuation. Only some phages, called *temperate*, can lysogenize as well, phages that cannot are called *virulent*. Finally, under special conditions one can obtain and perpetuate phage particles that can lysogenize but have lost the power to complete the lytic cycle of phage growth Such phages cannot reproduce themselves but give rise to so-called *defective* lysogenic cultures.

In medical contexts one thinks of virulence as a viral property subject to gain and loss, and phages possess comparable properties Perhaps unfortunately, the property called virulence in phages is not analogous to these; it is better to think of the temperate character as something that can be gained and lost. The term "virulence" refers to a specific defect in phage function, just as the term "defective" refers to another

The lytic and the lysogenic cycles are very different phases of viral growth, and much of this chapter will be devoted to their separate description During the lytic cycle, something having properties suggestive of a phage chromosome, and lacking many properties of phage particles, multiplies This something is called *vegetative phage*. During the lysogenic cycle, something having similar properties multiplies in a different way This something is called *prophage*. Mature phage particles are formed only during the lytic cycle, and these evidently contain something having the properties of a phage chromosome It is assumed, and experiment confirms, that the multiplication of vegetative phage, like the multiplication of prophage, precedes and is independent of a separate process, called *maturation*, giving rise to the mature particles

Phage growth can be thought of as a single cycle with a bypass, composed of at least 3 stages and 7 processes, as summarized in Figure 43. It can also be thought of as 2 alternative cycles, and this view is useful because phages confined to either one or the other are known, as mentioned above. In the following pages we present the lytic cycle first and describe lysogeny only after a large part of the biology of phage has been discussed This presentation is illogical but seems

to be simplest and has some historical justification.

RESTING PHAGE PARTICLES

Infectivity. Phage particles can be enumerated by various physical, chemical and biologic methods, of which only two need be mentioned here *Infective particles* are counted in terms of the number of clearings or *plaques* to which they give rise when introduced into an agar layer heavily seeded with bacteria sensitive to infection By suitable variations in technic one counts in this way free phage particles, infected bacteria, lysogenic bacteria, lysogenizing phage particles, or particles giving rise to lytic infection The total number of particles can be counted by quantitative electron microscopy In favorable instances from 50 to 100 per cent of the visible particles form plaques (Luria et al, 1951, Kellenberger and Arber, 1957)

Morphology. Probably all phages, with the possible exception of the smallest ones which have not yet been identified in electron micrographs, form tadpole-shaped particles (Williams and Fraser, 1953) The coliphage T2, one of the largest, consists of a polyhedral head, hexagonal in cross section, and a cylindrical tail In frozen-dried preparations, the head measures 65×95 mμ, and the tail 25×100 mμ The particles can be emptied of nucleic acid by osmotic shock, leaving a protein ghost closely resembling the intact particle in form (Anderson, 1953, Herriott, 1951) The phage particle consists, therefore, of a protein shell inside which the nucleic acid is rather tightly packed Micrographs are shown in Chapter 2

The tail of the T2 particle consists of a central pin running full length, surrounded by a tubular sheath (Kellenberger and Arber, 1955, Williams and Fraser, 1956) At the end of the tail are attached several fibrils usually visible only as a terminal thickening The manner of attachment of the fibrils is not clear The staphylococcal phage K probably is constructed in a manner similar to T2 (Hotchin, 1954)

Many other phages differ in size, shape and probably in structural detail, but all must be made along sufficiently similar lines to perform the common task, attachment to and puncture of the bacterial cell, and injection of nucleic acid Little is known about the smallest phages, but they probably measure about 20 mμ in diameter and contain only 1 3 to 13 per cent as much DNA per particle as T2 (Tessman et al, 1957)

Chemical Composition. All phages that have been examined, probably including one of the smallest (Sinsheimer, 1957), are composed chiefly of protein and DNA Detailed information is at hand only for T2, which contains approximately equal amounts of these two substances (2×10^{-16} Gm of each per particle) and little else Fractionation by osmotic shock is of special value, because it separates the particles into intact ghosts (empty protein shells) and nucleic acid This permits in principle the isolation of DNA, together with its possible chemical associates By combining this and other technics, an upper limit to the associates has been defined (Hershey, 1957b) The ghosts account for about 95 per cent of the organic material other than DNA The remainder of presumably internal constituents includes a small amount of a typical protein, a low molecular weight polypeptide of simple composition, one or two unidentified free amino acids, and two purine derivatives None of these minor components is well characterized, but each is distinct from the others None appears to be closely associated with the DNA

Antigenic Structure. All or nearly all phages are good antigens, and distinctly different phages are antigenically unrelated to each other They are always antigenically unrelated to their hosts Independently isolated phages obviously similar in other respects tend to be similar, but not identical, by serologic criteria Two phages differing only by one or two mutational steps are often serologically identical

Phage T2 presents at least two distinct surface antigens, apparently corresponding to head and tail proteins (Lanni and Lanni, 1953) Only the antibody directed against tail parts can neutralize the infectivity of phage particles Antibody against heads is detected by complement fixation Three functionally different types of antitail antibody have been found in serum prepared by immunization with T4, a coliphage similar to

T2 (Jerne, 1956, Jerne and Avegno, 1956) Therefore, different tail parts may correspond to different antigens. In addition, one can detect the usual multiple antigenic specificity by studying cross reactions. For example, T2 and T4 exhibit both common and specific antigenic determinants.

Phage T2 contains also an internal antigen, detectable only after osmotic shock, that is probably different from any in T4 or T6 (L Levine et al., 1957)

INITIAL STEPS OF INFECTION

The initial steps of infection include attachment of phage to bacterium and injection It is probably safe to assume that these steps are the same in lytic infection and in lysogenization, particularly since the decision between these alternatives can be influenced by experimental treatments applied some time after infection.

Primary Attachment. Several phages, perhaps all, attach to bacteria by the tips of their tails (Anderson, 1953) The attachment is exceedingly specific and determines, in part, the strains and the species of bacteria that a given phage can infect The primary reaction occurs between the attachment organ of the phage particle and receptor substances, often major antigens, present in the bacterial cell wall (Kellenberger and Arber, 1955, Weidel and Kellenberger, 1955, Jesaitis and Goebel, 1955). In T2, the terminal fibrils in the tail act as cementing substance (Williams and Fraser, 1956), and the tail pin punctures the cell wall (Kellenberger and Arber, 1955), apparently aided by an enzyme hidden in the tail (Brown and Kozloff, 1957) The attachment reaction also stimulates release of DNA (Jesaitis and Goebel, 1955), and the whole process is mimicked when T2 reacts with zinc complexes in solution (Kozloff et al, 1957) The interacting factors seem to be, tail fibrils and receptor substance; zinc protein in the cell wall and thiolester bonds holding the tail parts together (Kozloff and Lute, 1957); tail enzyme and bacterial substrate (not receptor substance) (Koch and Weidel, 1956)

In addition, phage-specific cofactors, chiefly various cations, must be present in the medium if attachment is to occur at all (reviewed by Tolmach, 1957). It is generally assumed that specific cation requirements imply specific effects in addition to those attributable to the reduction of electrostatic barriers, but clear evidence for this has not been obtained (Beumer et al, 1957). However, one such cofactor, L-tryptophan, required for the attachment of certain strains of T4, is thought to alter tail structure, possibly causing extension of tail fibrils in a process akin to reversible denaturation of proteins (Sato, 1956; Cheng, 1956) A pH-dependent, reversible alteration in the structure of T2, detected so far only by hydrodynamic methods (Taylor et al, 1955), suggests that one role of cations may be similar to that indicated for tryptophan

Injection. Injection of DNA, as a manner of penetration of phage into bacterium, can be demonstrated very simply by appropriate methods of electron-microscopy (Anderson, 1953) As an idea, it occurred more or less simultaneously to several people The first convincing experiment was performed by Hershey and Chase (1952) They prepared phage particles labeled in their DNA with radiophosphorus, or in their proteins with radiosulfur If either type of preparation was mixed with bacteria to permit attachment of phage particles and centrifuged, most of the radioactivity went down with the bacteria. This is, in fact, one useful method of measuring attachment of phage to bacteria If, however, the suspension of infected bacteria was first spun in a Waring blendor and then centrifuged, labeled DNA went down as before, but 80 per cent of the labeled phage protein was left in the supernatant fluid The infected bacteria submitted to this treatment remained competent to yield phage. The proper interpretation of these results called for additional experiments but will be obvious to the reader from the facts already summarized

The conditions specifically requisite for injection are not yet elucidated. Calcium ions are required for injection by T5 (Luria and Steiner, 1954). Metal chelators interfere with injection of T2 (Kozloff and Lute, 1957) T2 inactivated by dilute formaldehyde or by ionizing radiations does not inject efficiently but perhaps does not attach normally either (Hershey and Chase, 1952, Hershey et al, 1954). Dependence on bacterial metabolism is

suggested by the effects ("abortive infection") of such agencies as starvation, cyanide and low temperature (reviewed by Gots, 1958).

The question of what is injected, besides DNA, has been investigated in some detail (Hershey, 1957b) The detected substances include all or most of the minor components mentioned above: a typical soluble protein, a simple peptide, one or two free amino acids, and other trace substances probably too small in amount to be interesting The most massive fraction, the typical protein, weighs about 10^{-17} Gm per phage particle, or 4 per cent of the weight of the DNA In addition, however, the tail pin probably penetrates the cell wall, and its role in infection is not known Some of the tail parts presumably account for much of the 15 or 20 per cent of the protein of T2 that cannot be removed from infected cells by spinning in the blendor.

Once the cell walls of bacteria have been damaged, the "protoplasts" can be infected by degraded phage particles, possibly by phage DNA alone (Spizizen, 1957; D Fraser et al, 1957). Thus a large part of the injection apparatus, and its rigidly specific character, are concerned with penetration of the cell wall

INFERENCES I

The diversity of size and shape among particles of different phages, more or less correlated with variations in other properties such as antigenic structure and host specificity, provides a preliminary basis for recognizing diverse species and other taxonomic groups (Adams, 1958) This conclusion constitutes one half of the meaning of the word virus The other half resides in the chemical and functional simplicity of the resting particles and especially that of the multiplying particles to be described presently The two halves evidently comprise the whole of any general notion about viruses and show quite clearly how phages differ from other things subject to biologic classification

The manner in which infection occurs, by attachment at the cell surface and penetration of DNA, shows that most of the viral protein serves solely as a protective device and delivery mechanism for the DNA Only the latter, in co-operation with the bacterium and a few minor viral components of unknown use, can function directly to initiate viral growth. The suggestion is obvious that the phage chromosome as it occurs in the resting phage particle may be composed solely or mainly of DNA

Injection is a formidable task and, in T2, calls for an elaborate apparatus In resting phage particles, as in more complex organisms, the most complicated structures seem to be devoted to the most specialized tasks, and indeed this ought to be so, since stripped to essentials all things that grow must be very much alike At any rate it is with this optimistic hope that we turn to the consideration of other stages in the life cycle of phages

THE LYTIC CYCLE

Multiplication of Vegetative Phage. The term "vegetative phage" originally referred to an idea—that there existed an unknown, noninfective form in which phages multiply. It soon became evident that one must distinguish between multiplication in the lytic cycle and multiplication in lysogenic bacteria, hence, the terms "vegetative phage" and "prophage" A more exclusive definition is now possible and will better serve present needs *Vegetative phage is the structure whose production during the lytic cycle of phage growth coincides with the accumulation of the chromosomes of future phage particles* This definition is intended to exclude (1) all structures not essential to the replication of chromosomes and (2) all structures, whatever their role in replication, that are not incorporated into the final particles

The following experiments, important also for an understanding of phage growth in general, furnish the proof of existence of vegetative phage as defined above. In essence they are variations of the one-step growth experiment of Ellis and Delbruck (1939) in which one measures, instead of a total yield of phage released by spontaneous lysis of infected cells, the partial yields released by artificial lysis at various earlier times Such experiments, first described by Doermann (1952 and earlier) and Anderson and Doermann (1952) are performed as follows.

Bacteria are infected with a measured ratio of phage particles to bacteria, for example 1 to 10 to produce *single infections*, or 5 to 1

T2 (Jerne, 1956, Jerne and Avegno, 1956). Therefore, different tail parts may correspond to different antigens In addition, one can detect the usual multiple antigenic specificity by studying cross reactions For example, T2 and T4 exhibit both common and specific antigenic determinants

Phage T2 contains also an internal antigen, detectable only after osmotic shock, that is probably different from any in T4 or T6 (L Levine et al, 1957).

INITIAL STEPS OF INFECTION

The initial steps of infection include attachment of phage to bacterium and injection It is probably safe to assume that these steps are the same in lytic infection and in lysogenization, particularly since the decision between these alternatives can be influenced by experimental treatments applied some time after infection

Primary Attachment. Several phages, perhaps all, attach to bacteria by the tips of their tails (Anderson, 1953). The attachment is exceedingly specific and determines, in part, the strains and the species of bacteria that a given phage can infect. The primary reaction occurs between the attachment organ of the phage particle and receptor substances, often major antigens, present in the bacterial cell wall (Kellenberger and Arber, 1955, Weidel and Kellenberger, 1955, Jesaitis and Goebel, 1955) In T2, the terminal fibrils in the tail act as cementing substance (Williams and Fraser, 1956), and the tail pin punctures the cell wall (Kellenberger and Arber, 1955), apparently aided by an enzyme hidden in the tail (Brown and Kozloff, 1957) The attachment reaction also stimulates release of DNA (Jesaitis and Goebel, 1955), and the whole process is mimicked when T2 reacts with zinc complexes in solution (Kozloff et al, 1957). The interacting factors seem to be tail fibrils and receptor substance; zinc protein in the cell wall and thiolester bonds holding the tail parts together (Kozloff and Lute, 1957), tail enzyme and bacterial substrate (not receptor substance) (Koch and Weidel, 1956)

In addition, phage-specific cofactors, chiefly various cations, must be present in the medium if attachment is to occur at all (reviewed by Tolmach, 1957). It is generally assumed that specific cation requirements imply specific effects in addition to those attributable to the reduction of electrostatic barriers, but clear evidence for this has not been obtained (Beumer et al., 1957). However, one such cofactor, L-tryptophan, required for the attachment of certain strains of T4, is thought to alter tail structure, possibly causing extension of tail fibrils in a process akin to reversible denaturation of proteins (Sato, 1956; Cheng, 1956). A pH-dependent, reversible alteration in the structure of T2, detected so far only by hydrodynamic methods (Taylor et al, 1955), suggests that one role of cations may be similar to that indicated for tryptophan

Injection. Injection of DNA, as a manner of penetration of phage into bacterium, can be demonstrated very simply by appropriate methods of electron-microscopy (Anderson, 1953) As an idea, it occurred more or less simultaneously to several people The first convincing experiment was performed by Hershey and Chase (1952) They prepared phage particles labeled in their DNA with radiophosphorus, or in their proteins with radiosulfur. If either type of preparation was mixed with bacteria to permit attachment of phage particles and centrifuged, most of the radioactivity went down with the bacteria This is, in fact, one useful method of measuring attachment of phage to bacteria If, however, the suspension of infected bacteria was first spun in a Waring blendor and then centrifuged, labeled DNA went down as before, but 80 per cent of the labeled phage protein was left in the supernatant fluid The infected bacteria submitted to this treatment remained competent to yield phage The proper interpretation of these results called for additional experiments but will be obvious to the reader from the facts already summarized

The conditions specifically requisite for injection are not yet elucidated Calcium ions are required for injection by T5 (Luria and Steiner, 1954). Metal chelators interfere with injection of T2 (Kozloff and Lute, 1957). T2 inactivated by dilute formaldehyde or by ionizing radiations does not inject efficiently but perhaps does not attach normally either (Hershey and Chase, 1952; Hershey et al, 1954). Dependence on bacterial metabolism is

and how it is replicated. These questions present themselves mainly in chemical terms and meet with the difficulty that only genetic methods, as in Doermann's experiments, can identify vegetative phage. Before this difficulty could be overcome, much purely chemical investigation, begun by Cohen and pursued by numerous workers (Chap 3), was necessary. A few results of this work can be summarized as follows

In *Escherichia coli* infected with T2, all the DNA synthesized contains hydroxymethylcytosine and is phage precursor No bacterial DNA (containing cytosine) is formed Radiophosphorus incorporated into DNA subsequently appears in phage particles. The kinetics of the transfer process show that the average cell contains about 45 phage-equivalent units (2×10^{-16} Gm each) of DNA, much of it in a single metabolic pool to which 5 units per bacterium per minute are added by synthesis and from which 5 units per bacterium per minute are removed to make phage particles Moreover, if maturation of phage particles is prevented by inhibiting protein synthesis, the pool of phage precursor DNA can be built up to at least 3 times the normal size and yet function with normal kinetics if protein synthesis is subsequently allowed to resume. In this manner one can obtain phage particles whose DNA and protein have been synthesized at different times, showing that synthesis of phage precursor DNA is independent of synthesis of phage precursor protein (Hershey and Melechen, 1957)

In the experiments last mentioned, chloramphenicol was used to inhibit protein synthesis, and phage precursor DNA accumulated in the presence of that substance can be called "chloramphenicol DNA." One of the first questions about the chemistry of vegetative phage can then be put very simply Is chloramphenicol DNA and vegetative phage the same thing?

To answer this question it is necessary to determine whether chloramphenicol DNA already possesses significant properties in common with the chromosomes of resting phage particles. Of the several methods available for this test, only one has been applied successfully It depends on the well-supported hypothesis that ultraviolet light produces its characteristic effects on phage particles by directly damaging the chromosomal substance These effects, and evidence for the hypothesis, will be described in the section in this chapter called radiation genetics.

Tomizawa (1958) found that irradiation of chloramphenicol DNA in infected bacteria, followed by removal of chloramphenicol, leads to the production of noninfective phage particles possessing unmistakably the properties exhibited by phage particles that have themselves been irradiated. The number and the proportion of dead particles in the yield depends directly on the amount of phage precursor DNA present in the cells at the time of irradiation, showing that the photochemical lesions do not themselves replicate. If the amount of irradiated DNA is large, the yield consists almost exclusively of noninfective particles, a result consistent with the radiochemical finding that, when the amount of chloramphenicol DNA is large, the yield consists of particles containing almost exclusively chloramphenicol DNA. Irradiation before infection of the bacterial DNA, which is an indirect precursor of phage particles, does not cause the production of noninfective particles containing the phosphorus of the irradiated DNA Pending confirmation by other methods, these results can be taken as proof that vegetative phage, and therefore the chromosomes of phage particles themselves, are composed of DNA to the exclusion of all other known phage constituents (Hershey, 1957b)

The experiments just described, if correctly interpreted, establish a direct correlation between the synthesis of phage precursor DNA and the accumulation of radiation-sensitive chromosomes and therefore provide two methods for measuring the multiplication of vegetative phage Judging by the relatively precise chemical data (Hershey and Melechen, 1957) vegetative replication begins from 5 to 10 minutes after infection, soon reaches a constant rate of production of about 5 vegetative particles per bacterium per minute and produces a population containing a constant number of vegetative particles by the 20th minute However, the actual size of this population is unknown The average cell contains about 45 phage equivalent units of phage precursor DNA of which an uncertain fraction is vegetative phage and the remainder must be con-

to produce *multiple infections.* A few minutes later, any unadsorbed phage particles from the original input having been eliminated by antiserum or centrifugation, the culture is diluted to contain only about 1,000 bacteria per cc, which prevents further interactions between phage particles and bacteria. Titration by means of the plaque count method made at this time shows one plaque corresponding to each infected bacterium Another sample of the diluted culture, to which cyanide is added to stop phage growth, is lysed by mechanical vibration or other means and then titrated. This sample yields only a negligible number of plaques arising from infected bacteria that survived the lysing treatment The result is understandable, since the infecting phage particles were destroyed in the act of injection, and insufficient time has elapsed for the formation of new particles

By titrating samples lysed in the same way at different times one observes an *eclipse period* before the first infective phage particle is produced in the cell This is followed by a linear increase in number of infective particles up to the time of spontaneous lysis, after which the number remains constant By comparing different methods of lysis Doermann found that cyanide alone is sufficient to induce lysis after the end of the eclipse period, and now the experiment is usually performed by simply adding cyanide or chloroform to the samples to be titrated. The eclipse period for different phages varies from a few minutes to half an hour and is usually half as long as the *latent period* measured from the time of infection to the commencement of spontaneous lysis

The experiment yields direct information only about intracellular accumulation of infective phage particles This occurs, for phage T2 at 37°, at a linear rate of 3 to 8 phage particles per bacterium per minute, beginning 10 to 15 minutes after infection and continuing, under special conditions in which spontaneous lysis can be postponed, for 2 hours or more, sometimes yielding more than 1,000 particles per bacterium

Doermann (1953 and earlier) applied this technic to bacteria infected with *two mutant* phages, h and r13 of T2, between which a low frequency of genetic recombination can be observed. Previous work had shown that the recombinants arising in this cross do not appear in large intrabacterial clones and therefore must be formed relatively late during multiplication of the phage (Hershey and Rotman, 1949) However, Doermann found that the first few phage particles formed already included both parental and recombinant types. Therefore, he postulated a structure, called vegetative phage, capable of multiplying and containing the genetic determinants of future phage particles but lacking the infective property of phage particles According to this hypothesis, infectivity would have to be acquired by a second process, called maturation, by which vegetative particles are converted into the well-known finished form

What is the significance of the period of eclipse? It could be supposed that this represents the minimum time for a vegetative particle to mature in an infected bacterium, in which case the intrabacterial population of unfinished particles would consist mainly of a series of intermediate forms between vegetative phage and the final product. Visconti and Garen (1953) found, on the contrary, that a phage particle infecting a bacterium in which phage growth was already under way could contribute genetic markers to phage particles finished only 4 minutes later. For this and other reasons it is now believed that an infected bacterium contains numerous vegetative particles and eventually finished particles but relatively few particles in intermediate stages, and that most of the eclipse period is devoted to the preparation for, and the actual process of, vegetative reproduction

How does multiplication take place? Luria (1951) showed that mutations occurring during vegetative growth produce branching mutant clones of phage in individual bacterial cells. Thus each vegetative particle seems to have the capacity to multiply. If so, multiplication is a geometric process, and this step, at least, in the production of phage particles does not obey the assembly line principle.

The multiplication of vegetative phage has not yet been observed in a direct, quantitative manner, but methods are being developed for this purpose as described below.

Synthesis of Phage-Precursor DNA Given the idea that the unit of vegetative reproduction is something different from the familiar phage particle, one asks what it is

serum (Maaløe and Symonds, 1953), most accurately after fractional centrifugation to separate them from phage particles (Hershey, unpublished). The serologically specific protein not contained in phage particles, measured in this way, can be called surplus antigen (Hershey, 1956).

Surplus antigen is first formed in the cells a few minutes before phage particles appear. The amount increases rapidly, reaching a constant level of about 15 phage equivalent units (2×10^{-19} Gm. of sulfur each) per bacterium by the 20th minute after infection. Only about half of this material can be sedimented under conditions that throw down empty phage membranes. Much or all of it seems to be phage precursor material, as shown in two ways. First, one can measure an upper limit to the total phage precursor protein present in the cells by an independent tracer method (Hershey and Melechen, 1957). This method shows that the amount of phage precursor protein is approximately equal to the amount of surplus antigen, about 15 units per bacterium. Second, one can observe the flow of radiosulfur out of surplus antigen and its simultaneous incorporation into phage particles (Hershey, unpublished). This result confirms that most of the surplus antigen is in fact phage precursor, and therefore that most of the phage precursor protein in the cells is serologically specific.

These facts raise the question of how the 15 units of phage precursor protein and the 45 units of phage precursor DNA are associated in the cell. In lysates, no association can be detected (Watanabe et al., 1954). However, there must be some DNA-containing intermediates in the assembly of phage particles (Hershey and Melechen, 1957). The failure to find them may mean that their number is small, requiring the assembly process to be extremely rapid, or that the intermediate forms are too fragile to survive the lysing procedures.

The phenomenon of phenotypic mixing described below shows that, in mixed infections with T2 and T4, the tail parts of a single phage particle can be determined by both viral lineages. This suggests that tail proteins and DNA are made separately and later incorporated into phage particles, but perhaps other interpretations are possible. It must be concluded that the manner of association between phage precursor DNA and phage precursor protein by which vegetative phage is converted into resting phage is unknown.

The separation of protein synthesis and DNA synthesis during phage growth has been accomplished in the reverse manner to that seen in experiments employing chloramphenicol (Watanabe, 1957). Once DNA synthesis has begun in infected cells, large doses of ultraviolet light applied to them suppresses further DNA synthesis much more strongly than it suppresses synthesis of serologically specific phage protein. Protein synthesis is thus, in principle, independent of DNA synthesis. Moreover, Tomizawa's (1958) experiments described earlier show that the whole process of maturation to produce noninfective phage particles with functionally complete membranes can occur in cells containing almost exclusively irradiated DNA. Therefore, maturation is independent of many DNA functions on which phage growth as a whole depends.

Lysis. Little is known about the actual lysis of phage-infected bacteria. As mentioned earlier, enzymes are found among the tail parts of T2 and T4. These act on cell walls and presumably aid penetration at the time of infection. They are probably responsible for the phenomenon known as lysis from without, which is seen with the phages mentioned and few others (Visconti, 1953).

Jacob et al. (1957) have found an enzyme having some of the properties of lysozyme in lysates of bacteria infected with phage lambda. Among various defective lysogenic cultures, it is produced only in those that lyse after induction with ultraviolet light. The lysing enzyme may represent a surplus of the same enzyme manufactured for phage tails, which would thus perform a dual role in phage growth.

INFERENCES II

The lytic cycle of phage growth is characterized best by summarizing both successes and failures of the line of investigation outlined above.

Following infection, the first process of known significance is the production of phage precursor DNA. This DNA has been identi-

tained in particles further along on the way to becoming finished phages The upper limit to the number of vegetative particles, 45, corresponds to an upper limit to the generation time, 9 minutes, if reproduction is really geometric

One may ask whether the linear rate of DNA synthesis reflects the fixed number of vegetative phage particles that the cells must contain This is unlikely, since the rate is similar and approximately linear in the presence of chloramphenicol, where all the precursor DNA accumulates as vegetative phage Evidently, the rate of synthesis is not determined by the number of vegetative particles, except possibly at early times

Another method for measuring vegetative reproduction has been applied to questions about defective lysogeny and will be cited in connection with that subject

Preparation for DNA Synthesis. When bacteria are infected with T2, synthesis of bacterial DNA stops abruptly, and synthesis of phage precursor DNA begins only after a delay of several minutes What is occurring during the period of delay? Numerous evidences show that synthesis of protein is essential during this period (Chap. 3). For example, in the experiments with chloramphenicol discussed above, it is necessary to wait from 5 to 10 minutes after infection before adding the antibiotic to permit resumption of DNA synthesis This result is perhaps not surprising, since at least one new enzyme, which hydroxymethylates cytosine, is formed and presumably is required for growth of T2 (Chap 3) For other phages analogous requirements can be imagined

Radiobiologic experiments go much further in suggesting that the phage DNA itself, though essential to initiate DNA synthesis, is superfluous thereafter (reviewed by Stent, 1958). For example, ultraviolet light, which produces lethal damages in the DNA of phage particles, has relatively little effect on the DNA-synthesizing capacity of infected bacteria (Watanabe, 1957). At one time such results were interpreted to mean that vegetative phage itself was resistant to ultraviolet light. Tomizawa's (1958) experiments described above show that this is not so; only the capacity of infected cells to produce vegetative phages is resistant.

One way of explaining the radiobiologic findings is to suppose that the infecting phage particle organizes a radioresistant structure, composed of protein for example, that in turn can regenerate phage chromosomes (Stent, 1958). According to this hypothesis the basic mechanism of DNA synthesis could hardly be geometric

Another way of explaining the radiobiologic findings is to suppose that one or several irradiated chromosomes somehow can regenerate undamaged ones without being repaired themselves, but only provided that they have performed certain critical tasks before irradiation (Benzer, 1952; Krieg, 1957) According to this hypothesis, the radiobiologic experiments suggest clues concerning genetic recombination and other functions of DNA but do not prohibit DNA from playing a direct role in its own synthesis

At the present time the two interpretations are about equally unsatisfactory, but it is necessary to consider how to distinguish between them and to admit that this major gap exists in our understanding of DNA synthesis and phage growth.

Maturation. We concluded above that the synthesis of phage precursor DNA and the production of vegetative phage particles are a single process, which is independent of synthesis of phage precursor protein It follows that maturation comprises the whole sequence of processes by which preformed phage DNA is incorporated into finished phage particles. This includes the complete synthesis of several proteins, their organization into characteristic phage membranes, and, no less mysterious, the packing of DNA inside them

In experiments employing chloramphenicol, it is clear that the synthesis of phage precursor DNA precedes the start of maturation. In the formation of individual phage particles this also must be the normal sequence of events (Hershey and Melechen, 1957) Considering the infected cell as a whole, however, the two processes normally occur side by side.

Lysates of bacteria infected with T2 contain, besides completed phage particles, other morphologically and serologically recognizable phage-specific structures (Chap 3). The protein content of such structures can be measured as radiosulfur precipitable by antiphage

serum (Maaløe and Symonds, 1953), most accurately after fractional centrifugation to separate them from phage particles (Hershey, unpublished) The serologically specific protein not contained in phage particles, measured in this way, can be called *surplus antigen* (Hershey, 1956).

Surplus antigen is first formed in the cells a few minutes before phage particles appear. The amount increases rapidly, reaching a constant level of about 15 phage equivalent units (2×10^{-15} Gm of sulfur each) per bacterium by the 20th minute after infection Only about half of this material can be sedimented under conditions that throw down empty phage membranes Much or all of it seems to be phage precursor material, as shown in two ways First, one can measure an upper limit to the total phage precursor protein present in the cells by an independent tracer method (Hershey and Melechen, 1957) This method shows that the amount of phage precursor protein is approximately equal to the amount of surplus antigen, about 15 units per bacterium Second, one can observe the flow of radiosulfur out of surplus antigen and its simultaneous incorporation into phage particles (Hershey, unpublished) This result confirms that most of the surplus antigen is in fact phage precursor, and therefore that most of the phage precursor protein in the cells is serologically specific.

These facts raise the question of how the 15 units of phage precursor protein and the 45 units of phage precursor DNA are associated in the cell. In lysates, no association can be detected (Watanabe et al, 1954) However, there must be some DNA-containing intermediates in the assembly of phage particles (Hershey and Melechen, 1957). The failure to find them may mean that their number is small, requiring the assembly process to be extremely rapid, or that the intermediate forms are too fragile to survive the lysing procedures.

The phenomenon of phenotypic mixing described below shows that, in mixed infections with T2 and T4, the tail parts of a single phage particle can be determined by both viral lineages This suggests that tail proteins and DNA are made separately and later incorporated into phage particles, but perhaps other interpretations are possible It must be concluded that the manner of association between phage precursor DNA and phage precursor protein by which vegetative phage is converted into resting phage is unknown.

The separation of protein synthesis and DNA synthesis during phage growth has been accomplished in the reverse manner to that seen in experiments employing chloramphenicol (Watanabe, 1957) Once DNA synthesis has begun in infected cells, large doses of ultraviolet light applied to them suppresses further DNA synthesis much more strongly than it suppresses synthesis of serologically specific phage protein Protein synthesis is thus, in principle, independent of DNA synthesis Moreover, Tomizawa's (1958) experiments described earlier show that the whole process of maturation to produce noninfective phage particles with functionally complete membranes can occur in cells containing almost exclusively irradiated DNA Therefore, maturation is independent of many DNA functions on which phage growth as a whole depends

Lysis. Little is known about the actual lysis of phage-infected bacteria As mentioned earlier, enzymes are found among the tail parts of T2 and T4 These act on cell walls and presumably aid penetration at the time of infection They are probably responsible for the phenomenon known as lysis from without, which is seen with the phages mentioned and few others (Visconti, 1953)

Jacob et al (1957) have found an enzyme having some of the properties of lysozyme in lysates of bacteria infected with phage lambda Among various defective lysogenic cultures, it is produced only in those that lyse after induction with ultraviolet light The lysing enzyme may represent a surplus of the same enzyme manufactured for phage tails, which would thus perform a dual role in phage growth

INFERENCES II

The lytic cycle of phage growth is characterized best by summarizing both successes and failures of the line of investigation outlined above

Following infection, the first process of known significance is the production of phage precursor DNA This DNA has been identi-

fied with reasonable assurance as the chromosomes of future phage particles. Its production is independent of the production of phage precursor proteins Therefore, it is necessary to recognize a unit of reproduction, called vegetative phage, that might be described as nascent phage precursor DNA, composed, apparently, of DNA only

The phage particle is formed by a second process, called maturation, that calls for complete synthesis of phage proteins, their organization into phage membranes, and the inclusion of preformed DNA inside them The phage DNA apparently exerts its control over this process in an indirect manner, since it is clear that the maturation of a given particle is not dominated solely by the chromosome included in it, indeed, the latter may have been severely damaged by ultraviolet light before maturation started.

During a steady state period of phage growth, the T2 infected cell contains enough phage precursor DNA to make 45 phage particles and enough phage precursor protein to make about 15 Both precursors are formed at a rate equal to the rate at which they are used to make phage particles, about 5 phage particle equivalents per bacterium per minute.

Present methods do not permit one to distinguish between phage precursor DNA present in vegetative phage and in hypothetical intermediates in the process of maturation For this reason the above figures cannot yet be related to the kinetics of growth of vegetative phage

No weighty evidence has been obtained as to whether or not each vegetative phage particle serves as a center for its further reproduction, but again the question has been framed in quasi-experimental terms

GENETIC STRUCTURE AND FUNCTION

Mutations. Any heritable change in the properties of a phage arising in an initially homogeneous line may be called a mutation. The observed mutations in phage affect such characters as host range, plaque type, growth potential, latent period, ability to lysogenize, sensitivity to high temperatures, and dependence on cofactors. These categories are not mutually exclusive. For example, mutations affecting ability to lysogenize are usually recognized as alterations in plaque type, and mutations affecting host range are often accompanied by changes in sensitivity to heating. Because of the ease of recognizing them, only mutations affecting host range or plaque type are commonly used in genetic experiments.

The mutations that have been studied best show a few characteristic features in common. They occur exclusively during the growth of the phage, producing mixed yields of the original and mutant types in single infected bacteria (Luria, 1951). Mutagenic agents such as ultraviolet light, proflavine and bromouracil increase the frequency of phage mutations, but these agents are demonstrably effective only when applied to the bacteria, before infection (Jacob, 1954; Fraser, 1957), after infection (Latarjet, 1949, DeMars, 1953, Litman and Pardee, 1956), or separately to phage and bacteria (Weigle, 1953, Weigle and Dulbecco, 1953)

When analyzed by recombination tests, mutational changes are revealed as local changes in chromosome structure, which usually occur singly but can be accumulated by successive independent steps (Hershey and Rotman, 1948)

The frequencies of repetition of identical mutations are seldom measurable but probably vary at least over the range between 10^{-3} and 10^{-10} per phage produced (Streisinger and Franklin, 1956, Benzer, 1957) The frequencies of repetition of nonidentical mutations of similar type depend chiefly on structural requirements for genetic function (Hershey and Rotman, 1948; Streisinger and Franklin, 1956, Benzer, 1957) Thus, the loss of a particular function may be very frequent because alternative structural changes at many points interfere with it. On the other hand, the restoration of a function recently lost by mutation often calls for reversal of the original change and may be rare or frequent, depending on the idiosyncrasies of the first mutation In such cases the distinction between gain and loss of function seems to have meaning, one can recognize a "positive" functional state as one requiring a highly specified genetic configuration (Streisinger and Franklin, 1956).

Genetic Recombination. When a bacterium is infected with one or more particles of each of two closely related phages, preferably two different mutants of the same phage species, one obtains a yield of phage containing particles of the two parental types, plus a certain number of particles that obviously are derived by recombination of characters present in the parental phages. The rules governing the kinds of recombination observed are extremely simple, and the qualitative results can be predicted, with rare exceptions, from the mutational history of the stocks.

Suppose, for example, one has isolated from T2 a host range mutant, called h, capable of lysing a bacterial strain, called B/2, resistant to infection by T2. Secondly, one has isolated a rapidly lysing mutant, called r, that differs from T2 with respect to type of plaque. T2 itself may then be called h^+r^+, meaning simply not-h and not-r. The genetic crossing between the two mutants is performed by infecting bacteria with both simultaneously and examining the yield of new phage particles. The first notable result is the appearance of new types of phage. The simplicity of the result resides in the fact that all the particles, like their parents, can be classified as h or h^+, and as r or r^+, with respect to hereditary character. This is the reason for concluding that individual mutations generally correspond to single changes in genetic structure. Therefore, the only possible combinations of the characters are h^+r^+, hr, h^+r, and hr^+. The rule of recombination deduced from the experiment merely states that when two dissimilar phages are crossed, all the anticipated recombinations of the characters present in the parents will be found among the offspring. Thus, bacteria infected with the first and the second or with the third and the fourth of the genotypes listed above will yield all 4. Bacteria infected with any other pair, for example the first and the third genotypes, will yield only the parental combinations. This is the main justification for speaking of genetic recombination between phages (reviewed by Hershey, 1953).

In crosses involving a 2-factor difference, as in the example cited, a *recombination frequency* can be measured very simply. It is the ratio between the number of recombinant phage particles and the number of phage particles of all kinds counted in a sample of the progeny from the cross. What determines this frequency? Experiment shows that a number of conditions are important which, however, can be divided into 2 classes. First, several kinetic variables affect recombination frequency in approximately the same way that time and concentrations affect the progress of a chemical reaction. These variables have been analyzed in an elegant theory by Visconti and Delbrück (1953). Second, if all other variables are held constant, one sees that recombination frequency is markedly dependent on the particular pair of mutants chosen for the experiments. Under these conditions one measures *linkage* between the markers under test. This measurement is of importance because it leads to information about the structure of the phage chromosome. In short, one can show that mutations occur at various places along the length of a linear chromosome (Hershey and Rotman, 1948), that a phage particle contains only one such chromosome (Jacob and Wollman, 1955), and that physiologically related mutations tend to occur within short segments of it (Benzer, 1955).

The main conclusion deriving from analysis of the kinetic variables is that genetic recombination must be interpreted as the consequence of repeated random matings in a population of, presumably, vegetative phage particles. There are about 5 mating cycles during the growth of T2 and T4 in one bacterium, whereas most other phages that have been studied mate only about once. The difference is unexplained and presents a major challenge to current thought about mechanisms of recombination (Stent, 1958).

Heterozygosis. It was stated above that a phage particle issuing from an h × r cross must be either h or h^+ and either r or r^+ in gentoype. This is not quite so, a few exceptional particles yield clones that are mixed with respect to one character or the other. Such particles are partial heterozygotes (Hershey and Chase, 1951), containing large chromosomal segments from both parents with short overlapping regions (Levinthal, 1954). All observers have realized that the heterozygotes must be related to the manner of production of recombinants. For the present,

fied with reasonable assurance as the chromosomes of future phage particles Its production is independent of the production of phage precursor proteins Therefore, it is necessary to recognize a unit of reproduction, called vegetative phage, that might be described as nascent phage precursor DNA, composed, apparently, of DNA only

The phage particle is formed by a second process, called maturation, that calls for complete synthesis of phage proteins, their organization into phage membranes, and the inclusion of preformed DNA inside them. The phage DNA apparently exerts its control over this process in an indirect manner, since it is clear that the maturation of a given particle is not dominated solely by the chromosome included in it, indeed, the latter may have been severely damaged by ultraviolet light before maturation started

During a steady state period of phage growth, the T2 infected cell contains enough phage precursor DNA to make 45 phage particles and enough phage precursor protein to make about 15 Both precursors are formed at a rate equal to the rate at which they are used to make phage particles, about 5 phage particle equivalents per bacterium per minute

Present methods do not permit one to distinguish between phage precursor DNA present in vegetative phage and in hypothetical intermediates in the process of maturation For this reason the above figures cannot yet be related to the kinetics of growth of vegetative phage.

No weighty evidence has been obtained as to whether or not each vegetative phage particle serves as a center for its further reproduction, but again the question has been framed in quasi-experimental terms

GENETIC STRUCTURE AND FUNCTION

Mutations. Any heritable change in the properties of a phage arising in an initially homogeneous line may be called a mutation The observed mutations in phage affect such characters as host range, plaque type, growth potential, latent period, ability to lysogenize, sensitivity to high temperatures, and dependence on cofactors. These categories are not mutually exclusive. For example, mutations affecting ability to lysogenize are usually *recognized as alterations in plaque type*, and mutations affecting host range are often accompanied by changes in sensitivity to heating Because of the ease of recognizing them, only mutations affecting host range or plaque type are commonly used in genetic experiments

The mutations that have been studied best show a few characteristic features in common. They occur exclusively during the growth of the phage, producing mixed yields of the original and mutant types in single infected bacteria (Luria, 1951). Mutagenic agents such as ultraviolet light, proflavine and bromouracil increase the frequency of phage mutations, but these agents are demonstrably effective only when applied to the bacteria, before infection (Jacob, 1954, Fraser, 1957), after infection (Latarjet, 1949; DeMars, 1953, Litman and Pardee, 1956), or separately to phage and bacteria (Weigle, 1953, Weigle and Dulbecco, 1953)

When analyzed by recombination tests, mutational changes are revealed as local changes in chromosome structure, which usually occur singly but can be accumulated by successive independent steps (Hershey and Rotman, 1948).

The frequencies of repetition of identical mutations are seldom measurable but probably vary at least over the range between 10^{-3} and 10^{-10} per phage produced (Streisinger and Franklin, 1956; Benzer, 1957). The frequencies of repetition of nonidentical mutations of similar type depend chiefly on structural requirements for genetic function (Hershey and Rotman, 1948; Streisinger and Franklin, 1956, Benzer, 1957) Thus, the loss of a particular function may be very frequent because alternative structural changes at many points interfere with it. On the other hand, the restoration of a function recently lost by mutation often calls for reversal of the original change and may be rare or frequent, depending on the idiosyncrasies of the first mutation In such cases the distinction between gain and loss of function seems to have meaning, one can recognize a "positive" functional state as one requiring a highly specified genetic configuration (Streisinger and Franklin, 1956).

isolation of and discrimination among many similar mutants. Without attempting to describe here the technics, we summarize some typical conclusions (Benzer, 1955).

A certain class of r mutations in T4 occur in what is known as the *rII* region of the phage chromosome. This region is concerned with functions essential for the growth of T4 in a lysogenic derivative of *E. coli* K12, but not essential for growth in its nonlysogenic derivatives. The *rII* region can be subdivided by complementarity tests into 2 functionally distinct segments lying adjacent to each other, each segment measuring only a few units in length. In each segment, many mutations can occur that at the same time give rise to the *r* character and restrict the growth potential. The least distance between adjacent mutations separable by recombination measures only 0.02 units. The whole chromosome of T4 is 200 or more units long. If the unit of length is taken at face value, the whole chromosome contains at least 200/0.02 or 10,000 recombination points. Among the internal constituents of the phage particle, 2 only contain this many "joints." The DNA consists of about 200,000 nucleotide pairs, the internal protein contains about 35,000 amino acid residues. The computation evidently permits, but does not require, the chromosome to be composed of DNA. The remarkable feature of this work lies in the detail with which the functional topology of the phage chromosome, and of its mutational sites and combining units, can be described. On the one hand, this permits thorough testing of the fidelity of the description. On the other hand, it should facilitate future analysis of DNA function in physiologic and chemical terms.

Radiation Genetics. Irradiated phage particles possess diverse properties depending on the kind, the amount and the conditions of irradiation, the kind of phage and the conditions of test (Watson, 1952, Bowen, 1953). At the present time the effects of ultraviolet light and of disintegration of incorporated radiophosphorus are especially interesting because of many reasons for believing that these radiations produce mainly damages localized in the phage DNA. Genetic experiments with irradiated phages confirm this belief and yield further clues to DNA function.

Phages T2 and T4 "killed" by ultraviolet light have been studied most thoroughly (reviewed by Bowen, 1953). Bacteria infected with a single particle of such phages are themselves killed, but growth of the phage is blocked at an early step, as shown by failure of DNA synthesis (Vidaver and Kozloff, 1957). The irradiated particles show a number of remarkable properties, some of which can be described briefly as follows. *Photoreactivation* is observed by exposing bacteria infected with the irradiated particles to visible light. This causes phage growth to proceed in some of the bacteria (Dulbecco, 1955). The quantitative results for T2 can be interpreted to mean that 56 per cent of the damages produced by ultraviolet light are repaired in illuminated bacteria. *Multiplicity reactivation* can be observed by infecting bacteria with more than one irradiated particle. Some of the bacteria receiving several individually noninfective particles produce a viable phage progeny (Luria and Dulbecco, 1949). This effect can be interpreted to mean that two or more radiation-damaged particles sometimes cooperate to bypass the damages. *Cross reactivation* occurs when bacteria are infected with a mixture of irradiated and unirradiated particles. To observe it the particles must be genetically marked. Under these conditions the yields of phage from individual bacteria often show markers contributed by the irradiated phage particles. Quantitative experiments show that individual markers, not whole phage particles, are reactivated. For this reason the phenomenon is now often called *marker rescue* (Doermann et al., 1955).

Photoreactivation focuses attention on the nature of the photochemical damage produced by ultraviolet light and the manner in which

system (Goodgal et al., 1957), it is probable that the damages are directly repaired (see also Lennox et al., 1954). The chemistry is obscure.

Cross reactivation and multiplicity reactivation are thought to occur not by chemical restoration of damaged DNA but by genetic reassortment of undamaged parts (Doermann et al., 1955). For the present, therefore, one can ignore the chemistry and focus on genetic mechanisms. Cross reactivation may reflect in

however, they serve mainly to point up our ignorance of how recombination really occurs.

Interspecific Crosses. The recombination method permits one to analyze genetic differences between two closely related phage species, thus making available differences that cannot be observed among mutants of the same phage For example, T2 and T4 differ serologically. In crosses between them, this difference segregates as a single factor that controls both serologic specificity and specificity of attachment to bacteria (Streisinger, 1956a) This result tends to show that both properties should be referred to the same component of the tail of the phage particle.

T2 and T4 also differ with respect to the glucose content of their DNA (Sinsheimer, 1956; Jesaitis, 1957). This difference does not readily segregate in crosses; all particles tend to resemble the T4 parent in glucose content and certain other properties (Streisinger and Weigle, 1956) It is not clear whether this result signifies an unusual kind of inheritance or merely reflects one or another complication likely to be encountered in interspecific crosses

Phenotypic Mixing. When bacteria are infected with two phages differing mainly or exclusively in host range, for example T2 and T4, many particles in the progeny exhibit an abnormal host range specificity. The abnormality may be described as lack of correspondence between genotype and phenotype (Novick and Szilard, 1951). Not only do such particles fail to breed true to type, but some of them exhibit a mixed phenotype, with both T2-like and T4-like character. As far as known, only the host range character, and the related serologic specificity and sensitivity to heat, are affected (Streisinger, 1956b). Evidently, this means that in a mixed infection the character of the tail protein of a given phage particle is often determined not by the genetic material in that particle but by the action of viral genes present in the cell as a whole. It remains to be learned whether or not this is a general characteristic of the protein structures of phage particles, and at what level of organization it makes its appearance.

Chromosome Structure. The recombination tests by which one measures linkage between different mutational markers in the phage chromosome yield information principally about distances between markers, and order of arrangement. Genetic map distances are measured in recombination units, the unit of length being 1 per cent recombination frequency. Map distances are assumed to be related more or less directly to physical distances. Order of arrangement is inferred from the following principle. If 3 markers are linked in the order abc, separation of b from the other two by recombination will be a relatively rare event Linearity of structure, now established with great precision for small distances, is inferred from the additivity of distances and their consistency with tests of order.

The precision of the genetic analysis of chromosome structure depends chiefly on the number of mutations that can be discriminated by recombination tests. However, the power of the analysis lies in the possibility of recognizing mutations affecting different chromosomal functions The latter is accomplished (1) in terms of the visible effects of the different mutations and (2) by the test of complementarity If 2 phage particles exhibiting similar but nonidentical mutations can carry out, in mixed infection, a function of which each alone is incapable, the mutations are said to affect different functions If the 2 particles fail, their mutations affect the same function This method of analysis identifies a functionally unitary region of the chromosome only to the extent that the results of complementarity tests, the visible effects of the mutations concerned, and their disposition on the genetic map yield consistent interpretations In addition, one now expects a loss of function resulting from mutation to be made good only by reversal of the original mutation, potentially a rare event (Streisinger and Franklin, 1956). These principles, excepting perhaps the last mentioned, are not new, they form part of the classic tradition of genetics. The remarkable current development is their more or less thorough validation for 9 functionally unitary segments in chromosomes of 4 different phages, a result by no means anticipated by the workers concerned (Benzer, 1955, 1957; Streisinger and Franklin, 1956, M. Levine, 1957; Kaiser, 1957). Needless to say, these successes depend partly on the discovery of favorable materials and partly on technical inventions permitting the

isolation of and discrimination among many similar mutants Without attempting to describe here the technics, we summarize some typical conclusions (Benzer, 1955)

A certain class of r mutations in T4 occur in what is known as the *rII region* of the phage chromosome This region is concerned with functions essential for the growth of T4 in a lysogenic derivative of *E coli* K12, but not essential for growth in its nonlysogenic derivatives The rII region can be subdivided by complementarity tests into 2 functionally distinct segments lying adjacent to each other, each segment measuring only a few units in length In each segment, many mutations can occur that at the same time give rise to the r character and restrict the growth potential. Radiation Genetics Irradiated phage particles possess diverse properties depending on the kind the amount and the conditions of irradiation, the kind of phage and the conditions of test (Watson, 1952, Bowen, 1953) At the present time the effects of ultraviolet light and of disintegration of incorporated radiophosphorus are especially interesting because of many reasons for believing that these radiations produce mainly damages localized in the phage DNA Genetic experiments with irradiated phages confirm this belief and yield further clues to DNA function

Phages T2 and T4 "killed" by ultraviolet light have been studied most thoroughly (reviewed by Bowen, 1953). Bacteria infected with a single particle of such phages are themselves killed, but growth of the phage is blocked at an early step, as shown by failure of DNA synthesis (Vidaver and Kozloff, 1957). The irradiated particles show a number of remarkable properties, some of which can be described briefly as follows. *Photoreactivation* is observed by exposing bacteria infected with the irradiated particles to visible light. This causes phage growth to proceed in some of the bacteria (Dulbecco, 1955) The quantitative results for T2 can be interpreted to mean that 56 per cent of the damages produced by ultraviolet light are repaired in illuminated bacteria *Multiplicity reactivation* can be observed by infecting bacteria with more than one irradiated particle Some of the bacteria receiving several individually noninfective particles produce a viable phage progeny (Luria and Dulbecco, 1949) This effect can be interpreted to mean that two or more radiation-damaged particles sometimes cooperate to bypass the damages *Cross reactivation* occurs when bacteria are infected with a mixture of irradiated and unirradiated particles To observe it the particles must be genetically marked Under these conditions the yields of phage from individual bacteria often show markers contributed by the irradiated phage particles. Quantitative experiments show that individual markers, not whole phage particles, are reactivated For this reason the phenomenon is now often called *marker rescue* (Doermann et al, 1955)

Photoreactivation focuses attention on the nature of the photochemical damage produced by ultraviolet light and the manner in which it is repaired or bypassed by cellular processes aided by visible light Since photoreactivation of isolated DNA has been observed in another system (Goodgal et al, 1957), it is probable that the damages are directly repaired (see also Lennox et al, 1954) The chemistry is obscure

Cross reactivation and multiplicity reactivation are thought to occur not by chemical restoration of damaged DNA but by genetic reassortment of undamaged parts (Doermann et al, 1955) For the present, therefore, one can ignore the chemistry and focus on genetic mechanisms Cross reactivation may reflect in

part normal mechanisms of genetic recombination, in part a secondary effect of ultraviolet light that increases the frequency of recombination. In both T2 and lambda phages the second effect can be demonstrated directly in genetic crosses, even, in phage lambda, by doses of ultraviolet light too small to produce appreciable inactivation of phage particles (Jacob and Wollman, 1955).

The results of quantitative marker rescue experiments can be interpreted in the following way (Krieg, 1957). Since even small doses of ultraviolet light cause apparent marker inactivation, radiation damages at a considerable distance from the marker being tested can prevent rescue In fact, the apparent target size of a single marker for small doses of light is 8 to 10 per cent of that for killing of the whole phage particle. This presumably means that a given marker in particles receiving 10 lethal damages of radiation is potentially rescuable but has only about an even chance of being rescued or not under the given conditions of test. As the dosage of radiation is increased, the sensitivity of the surviving markers decreases, reaching, at very high doses, an apparent target size that is only about 0 7 per cent of that for primary lethal effects The potentially rescuable markers surviving high doses are rescued with a probability of only 0 02. The effects of increasing dosage are understood as follows It is supposed that, once a given marker has been bracketed by radiation damages, further damages are without effect unless they fall within the bracket This implies that the probability of rescue is determined mainly by the size of the bracket and vanishes at a certain minimum size.

The results so far described could perhaps be interpreted in different ways, without invoking persistent, localized damages to genetic material, or rescue by genetic recombination. However, two additional experiments support the orignal interpretation.

Hershey and Burgi (1956) showed by tracer experiments that the offspring from a [illegible]

[illegible]

from the irradiated parent This shows that the radiation damages persist during infection and remain associated with the DNA of the irradiated particles.

Krieg (1957) correlated the inactivation by ultraviolet light of a specific chromosomal function with the loss of a genetic marker lying in the appropriate chromosomal region Recall that in a mixed infection with T4r$^+$ particles and rII mutant particles, both phages can multiply in a lysogenic derivative of *E. coli* K12, the genetic defect of the mutant particles being made good by the competence of the others. If the mixed infection is brought about with irradiated T4r$^+$ particles and unirradiated mutant particles, some bacteria yield phage, and some do not Among the individual yields, Krieg found a high frequency of r$^+$ marker rescues, as compared with rescues of another marker lying outside the rII chromosomal region However, in identical experiments employing a nonlysogenic strain of *E coli*, the two markers are rescued with equal frequency These experiments reveal a radiation-sensitive structure in T4 that is specifically required for growth in lysogenic K12, whose function tends to be destroyed simultaneously with losses of the r$^+$ marker. This structure is evidently the rII region of the phage chromosome identified by Benzer (1955). It follows that the radiation damages detected in marker rescue experiments are in fact chromosomal damages, and that the probabilty of rescue is determined in part by the chromosomal distances between the sites of damage and the marker under test Other evidence suggests that a large fraction, though perhaps not all, of the damages produced in phage particles by ultraviolet light are of this type (Doermann et al , 1955)

Marker rescue is also observed in comparable experiments with phage inactivated by decay of assimilated radiophosphorus (Stent, 1953; Stahl, 1956). Since the phosphorus in phage particles is contained in DNA, the damages must be localized in DNA (Stent and Fuerst, 1955), which means, at least in part, chromosomal damages The P^{32} decay method has been used in many ingenious ways, chiefly by Stent and his collaborators, to answer questions about DNA structure and function Some of these are mentioned in appropriate contexts in this chapter. In general, though not always in detail, the results parallel those obtained by comparable experiments using

ultraviolet light, confirming that both agents act primarily on DNA to produce chromosomal lesions

Transfer of Nucleic Acid from Parental to Offspring Phage. Putnam and Kozloff (1950) showed that labeled phosphorus contained in a parental generation of phage particles reappeared among the offspring particles. This suggested that one of the ways of learning something about how DNA performs its work would be to look at the mechanism of transfer The initial questions have now been answered with reasonable certainty (reviewed by Hershey and Burgi, 1956; Hershey, 1957b) Only DNA is transferred The transfer is potentially highly efficient It occurs, at least in part, in the form of large functionally specific pieces Therefore, by the appropriate use of isotopes it is possible to examine molecules of DNA before and after they have performed their multiple functions

The evidence for transfer of DNA in functional form is 4-fold Decay of transferred radiophosphorus occurring in the offspring particles can cause their death (Stent and Jerne, 1955) Some of the transferred pieces are very large (Levinthal, 1956) In genetic crosses, some of the transferred radiophosphorus remains preferentially associated with the genotype of the radioactive parent (Hershey and Burgi, 1956) In mixed infections with irradiated phage, some of the offspring particles receiving DNA from the irradiated parent are in consequence noninfective (Hershey and Burgi, 1956)

If radiations produce chromosomal lesions, as previously concluded, the transfer experiments reveal transfer of chromosomal DNA In addition, some of the experiments seem to show that part of the transferred DNA, at least, is not subject to progressive fragmentation during growth (Levinthal, 1956, Delbruck and Stent, 1957)

These solid gains are overshadowed at the moment by a new problem arising partly from the experiments cited It now appears that the DNA of T2 is composed of 2 fractions differing in molecular weight (Levinthal, 1956), in chemical composition (Brown and Martin, 1956) and in sensitivity to ultraviolet light (Hershey and Burgi, 1956) Some of the evidence for distinct fractions is purely formal, and all of it is rather preliminary. However, the question is raised whether phage particles may not contain both chromosomal and nonchromosomal DNA. Until this question is decided, the proper interpretation of the transfer experiments, and what clues they can yield concerning DNA function, remain obscure A related area of ignorance should be kept in mind Is the chromosome of T2 a single linear molecule of DNA or a bundle of molecules?

INFERENCES III

The particle of several phage species contains a single linear chromosome differentiated along its length into segments each of which has its own prescribed function Each segment is subject to mutation and is further subdivisible by genetic recombination at many points The units of physiologic action span only a small length of chromosome and appear to be continuous and nonoverlapping There is a strong suggestion that adjacent units of action tend to have related functions This manner of organization presumably reflects requirements for the concerted replication of segments and to a lesser extent requirements for concerted physiologic action Whatever the requirements for integration may be, it appears to be useful and permissible for the present to think of different segments as performing their functions independently of other segments

The analysis of these functions in chemical terms is all to come Some appreciation of the missing knowledge may be gained by comparing a typical problem in chemical genetics with a typical problem in pharmacology; the action of the simplest drugs on cells is seldom understood The power of genetic analysis, well illustrated by the work with phage, lies in its ability to circumvent chemical ignorance Of course, this does not justify chemical ignorance

The information about the phage chromosome is broadly similar to information about chromosomes in general The special interest in the phage chromosome derives from its small size and from evidence that it is composed solely of DNA, perhaps a single molecule of DNA. What is this evidence?

All of it, so far, begins with the proof that

part normal mechanisms of genetic recombination, in part a secondary effect of ultraviolet light that increases the frequency of recombination. In both T2 and lambda phages the second effect can be demonstrated directly in genetic crosses, even, in phage lambda, by doses of ultraviolet light too small to produce appreciable inactivation of phage particles (Jacob and Wollman, 1955).

The results of quantitative marker rescue experiments can be interpreted in the following way (Krieg, 1957). Since even small doses of ultraviolet light cause apparent marker inactivation, radiation damages at a considerable distance from the marker being tested can prevent rescue. In fact, the apparent target size of a single marker for small doses of light is 8 to 10 per cent of that for killing of the whole phage particle. This presumably means that a given marker in particles receiving 10 lethal damages of radiation is potentially rescuable but has only about an even chance of being rescued or not under the given conditions of test. As the dosage of radiation is increased, the sensitivity of the surviving markers decreases, reaching, at very high doses, an apparent target size that is only about 0.7 per cent of that for primary lethal effects. The potentially rescuable markers surviving high doses are rescued with a probability of only 0.02. The effects of increasing dosage are understood as follows. It is supposed that, once a given marker has been bracketed by radiation damages, further damages are without effect unless they fall within the bracket. This implies that the probability of rescue is determined mainly by the size of the bracket and vanishes at a certain minimum size.

The results so far described could perhaps be interpreted in different ways, without invoking persistent, localized damages to genetic material, or rescue by genetic recombination. However, two additional experiments support the orignal interpretation.

Hershey and Burgi (1956) showed by tracer experiments that the offspring from a mixed infection with irradiated and live phage particles includes a few noninfective particles containing large pieces of DNA transmitted from the irradiated parent. This shows that the radiation damages persist during infection and remain associated with the DNA of the irradiated particles.

Krieg (1957) correlated the inactivation by ultraviolet light of a specific chromosomal function with the loss of a genetic marker lying in the appropriate chromosomal region. Recall that in a mixed infection with T4r$^+$ particles and rII mutant particles, both phages can multiply in a lysogenic derivative of *E. coli* K12, the genetic defect of the mutant particles being made good by the competence of the others. If the mixed infection is brought about with irradiated T4r$^+$ particles and unirradiated mutant particles, some bacteria yield phage, and some do not. Among the individual yields, Krieg found a high frequency of r$^+$ marker rescues, as compared with rescues of another marker lying outside the rII chromosomal region. However, in identical experiments employing a nonlysogenic strain of *E. coli*, the two markers are rescued with equal frequency. These experiments reveal a radiation-sensitive structure in T4 that is specifically required for growth in lysogenic K12, whose function tends to be destroyed simultaneously with losses of the r$^+$ marker. This structure is evidently the rII region of the phage chromosome identified by Benzer (1955). It follows that the radiation damages detected in marker rescue experiments are in fact chromosomal damages, and that the probability of rescue is determined in part by the chromosomal distances between the sites of damage and the marker under test. Other evidence suggests that a large fraction, though perhaps not all, of the damages produced in phage particles by ultraviolet light are of this type (Doermann et al., 1955).

Marker rescue is also observed in comparable experiments with phage inactivated by decay of assimilated radiophosphorus (Stent, 1953; Stahl, 1956). Since the phosphorus in phage particles is contained in DNA, the damages must be localized in DNA (Stent and Fuerst, 1955), which means, at least in part, chromosomal damages. The P^{32} decay method has been used in many ingenious ways, chiefly by Stent and his collaborators, to answer questions about DNA structure and function. Some of these are mentioned in appropriate contexts in this chapter. In general, though not always in detail, the results parallel those obtained by comparable experiments using

quency of lysogenization often depends on the physiologic state of the bacteria before infection, on the multiplicity of infection, and on experimental treatments applied after infection In particular, lowering the temperature (G Bertani, 1953) or inhibiting protein synthesis (L E Bertani, 1957) during a critical period following infection causes many of the bacteria that otherwise would lyse to survive and yield lysogenic descendents However, the initially infected bacterium does not become lysogenic, it multiplies to produce a number of cells, including some that lyse, some that are uninfected, and one or more that initiate stable lysogenic clones (Lieb, 1953) These facts show that the alternative to prompt lysis is a prelysogenic state during which the material from the infecting phage particle remains multipotent and behaves neither as vegetative phage nor as prophage Perhaps it fails to multiply but has not yet become attached to the bacterial chromosome However, it is clear that it does not long remain inert, because sensitivity to decay of constituent radiophosphorus is lost within 20 minutes, both in cells that are going to lyse and in those to become lysogenic (Stent and Fuerst, 1956) This suggests that very little of the DNA of the infecting phage is incorporated into the prophage to which it eventually gives rise On the contrary, the DNA "primer" seems to have carried out all its radiosensitive functions soon after infection, whatever the consequences of the infection may be

Immunity. From the facts just given, it appears that lysogenization, and hence the temperate character, depends first of all on some frequent early failure in the lytic cycle of phage growth In a *Salmonella* phage, at least, this can be attributed to the early production of an active immunity, not to an intrinsically feeble capacity to initiate vegetative reproduction (reviewed by Hershey, 1957a)

Once lysogeny is established, a very solid immunity to the carried phage is evident Lysogenic bacteria seldom lyse spontaneously, they do not lyse when reinfected with the phage they carry or with many of its relatives, nor do they as a rule become doubly lysogenic when similarly reinfected

It is plausible to attribute the immunity against double lysogenization to steric factors, if there is a characteristic site for each prophage a duplicate should be forbidden (Lwoff, 1953) The immunity to lytic development may also be related in some way to the prophage site Jacob and Wollman (1957) analyzed 14 temperate phages selected for their failure to show cross immunity. All of them proved to occupy different prophage sites in *E. coli* K12 This could mean either that immunity to lytic development has a steric basis (Lwoff, 1953) or that highly specific immune substances are involved (Bertani, 1956).

Induction. Exposure of some lysogenic bacteria to ultraviolet light sets in train the lytic cycle of phage growth in all or most of the cells At the same time the immunity to superinfection is abolished. Evidently, the inducing agent lifts the immunity in both senses The phenomenon is called induction and is reviewed by Jacob and Wollman (1953)

In a single species of bacterium, some prophages are inducible, and others are not In *E coli* K12, inducible prophages are found to occupy various sites in a cluster near the galactose fermentation markers of the bacterial chromosome In the same bacterium, noninducible prophages occupy sites in other regions A number of the inducible phages, although occupying different prophage sites and not showing cross immunity in lysogenic bacteria, are serologically related and genetically intercrossable (Jacob and Wollman, 1957) This correlation between phage properties and prophage region is unexpected and introduces new considerations into the difficult problem of phage taxonomy

Lysogenic Conversion. The presence of a prophage in a lysogenic culture affects bacterial properties in a variety of ways that are not always predictable Besides the propensity toward spontaneous and induced phage production, and the prophage specific immunity, several characters associated with the lysogenic state have been described Only two examples will be mentioned here

Burnet (1934) had noted a constant association of certain phages with specific bacterial types in *Salmonella* In a well-known example, lysogenization of certain bacterial species of group E1 (antigens 3, 10) with phages carried by group E2 converts the recipient bacteria into strains of group E2

ultraviolet light produces chromosomal lesions. From this point there are 3 lines of evidence. First, typical radiation sensitive structures accumulate in infected bacteria subjected to the action of chloramphenicol, which permits synthesis of phage DNA but prevents synthesis of all other important phage precursors. Second, DNA and typical radiation-sensitive structures, but no other important phage constituents, pass from parental to offspring phage particles during growth Third, ultraviolet light and decay of incorporated radiophosphorus produce similar effects on phage particles, whereas ionizing radiations produce more diverse effects Only DNA, among phage constituents, could show the pattern of radiosensitivity exhibited by phage chromosomes Efforts are being continued to make these 3 lines of evidence independent of each other, and a fourth one (Fraser et al, 1957) may be forthcoming If this proof is sustained, the information about chromosomal function outlined above is also information about function of DNA

THE LYSOGENIC CYCLE

Lysogeny A lysogenic bacterial culture is one in which the cells multiply normally but possess and transmit to their descendents the potentiality to produce bacteriophage This potentiality is seldom expressed under ordinary conditions, a typical lysogenic culture may yield phage in 1 cell per 10,000 per bacterial generation The rate of spontaneous production is necessarily low because the production of phage is lethal to the bacterium.

Apart from the few cells already on the way to lysis, lysogenic bacteria do not contain demonstrable phage particles. Therefore, it is concluded that lysogenic bacteria contain a phage-specific structure, called prophage, that serves as a hereditary determinant of lysogeny. Since prophage must contain a chromosome genetically equivalent to that of the resting phage particle on the one hand, and functionally comparable with other determinants of bacterial heredity on the other, it is natural to assume a common component for all three, namely, DNA.

Lysogenic strains of many bacterial species occur rather frequently in natural environments and may be more frequent than suspected, because often the lysogenic character must go unrecognized, owing to lack of means for detecting the carried phages

Lysogeny is reviewed by Jacob and Wollman (1957) and G. Bertani (1958).

Prophage. The concept of prophage is justified by the following evidence that a singly lysogenic bacterium differs from a comparable nonlysogenic one by the possession of a single phage-specific structure per bacterial nucleus, which occupies a chromosomal site that is characteristic for the carried phage.

1 Lysogenic cultures identical with the natural ones are readily produced by infecting bacteria with appropriate phages, as discussed below.

2 Lysogenic cultures, after exposure to radiation, occasionally yield nonlysogenic cells These can be reinfected to restore the lysogenic condition (Lederberg and Lederberg, 1953).

3. Lysogenic bacteria do not yield infective phage particles when lysed artificially (Burnet and McKie, 1929). Neither do they contain antigens characteristic of phage particles (Miller and Goebel, 1954).

4. Defective lysogenic bacteria can often be caused to lyse by ultraviolet light. In some instances the lysates do not contain any morphologically recognizable phagelike structures (Arber et al, 1957).

5 A number of different prophages have been established in *E coli* K12 Each of these proves, in crosses between lysogenic and nonlysogenic bacteria, to occupy a different site on the bacterial chromosome (Jacob and Wollman, 1957). In a strain of *Shigella*, the prophage P2 can occupy 3 different sites, but 1 of them is preferred (G Bertani, 1956). With some exceptions of uncertain significance, a lysogenic culture cannot carry 2 genetically marked but otherwise identical prophages

6. The expectation that prophage contains phosphorus is supported by experiments of Stent et al (1957) which suggest, in fact, that the prophage and the resting phage particle contain identical amounts of DNA, as determined by sensitivity to decay of incorporated radiophosphorus

Lysogenization. When a sensitive bacterial culture is infected with a temperate phage, some of the cells lyse, and some of them multiply to yield lysogenic clones The fre-

quency of lysogenization often depends on the physiologic state of the bacteria before infection, on the multiplicity of infection, and on experimental treatments applied after infection In particular, lowering the temperature (*G Bertani, 1953*) or *inhibiting protein* synthesis (L. E Bertani, 1957) during a critical period following infection causes many of the bacteria that otherwise would lyse to survive and yield lysogenic descendents However, the initially infected bacterium does not become lysogenic, it multiplies to produce a number of cells, including some that lyse, some that are uninfected, and one or more that initiate stable lysogenic clones (Lieb, 1953) These facts show that the alternative to prompt lysis is a prelysogenic state during which the material from the infecting phage particle remains multipotent and behaves neither as vegetative phage nor as prophage Perhaps it fails to multiply but has not yet become attached to the bacterial chromosome However, it is clear that it does not long remain inert, because sensitivity to decay of constituent radiophosphorus is lost within 20 minutes, both in cells that are going to lyse and in those to become lysogenic (Stent and Fuerst, 1956) This suggests that very little of the DNA of the infecting phage is incorporated into the prophage to which it eventually gives rise On the contrary, the DNA "primer" seems to have carried out all its radiosensitive functions soon after infection, whatever the consequences of the infection may be

Immunity. From the facts just given, it appears that lysogenization, and hence the temperate character, depends first of all on some frequent early failure in the lytic cycle of phage growth In a *Salmonella* phage, at least, this can be attributed to the early production of an active immunity, not to an intrinsically feeble capacity to initiate vegetative reproduction (reviewed by Hershey, 1957a)

THE LYSOGENIC CYCLE

Lysogeny. A lysogenic bacterial culture is one in which the cells multiply normally but possess and transmit to their descendents the potentiality to produce bacteriophage This potentiality is seldom expressed under ordinary conditions, a typical lysogenic culture may yield phage in 1 cell per 10,000 per bacterial generation The rate of spontaneous production is necessarily low because the production of phage is lethal to the bacterium

Apart from the few cells already on the way to lysis, lysogenic bacteria do not contain demonstrable phage particles Therefore, it is concluded that lysogenic bacteria contain a phage-specific structure, called prophage, that serves as a hereditary determinant of lysogeny. Since prophage must contain a chromosome genetically equivalent to that of the resting phage particle on the one hand, and functionally comparable with other determinants of bacterial heredity on the other, it is natural to assume a common component for all three, namely, DNA

Lysogenic strains of many bacterial species occur rather frequently in natural environments and may be more frequent than suspected, because often the lysogenic character must go unrecognized, owing to lack of means for detecting the carried phages

Lysogeny is reviewed by Jacob and Wollman (1957) and G. Bertani (1958).

Prophage. The concept of prophage is justified by the following evidence that a singly lysogenic bacterium differs from a comparable nonlysogenic one by the possession of a single phage-specific structure per bacterial nucleus, which occupies a chromosomal site that is characteristic for the carried phage.

1. Lysogenic cultures identical with the natural ones are readily produced by infecting bacteria with appropriate phages, as discussed below.

2 Lysogenic cultures, after exposure to radiation, occasionally yield nonlysogenic cells These can be reinfected to restore the lysogenic condition (Lederberg and Lederberg, 1953).

3. Lysogenic bacteria do not yield infective phage particles when lysed artificially (Burnet and McKie, 1929) Neither do they contain antigens characteristic of phage particles (Miller and Goebel, 1954).

4 Defective lysogenic bacteria can often be caused to lyse by ultraviolet light In some instances the lysates do not contain any morphologically recognizable phagelike structures (Arber et al, 1957)

5 A number of different prophages have been established in *E coli* K12. Each of these proves, in crosses between lysogenic and nonlysogenic bacteria, to occupy a different site on the bacterial chromosome (Jacob and Wollman, 1957) In a strain of *Shigella*, the prophage P2 can occupy 3 different sites, but 1 of them is preferred (G Bertani, 1956) With some exceptions of uncertain significance, a lysogenic culture cannot carry 2 genetically marked but otherwise identical prophages

6. The expectation that prophage contains phosphorus is supported by experiments of Stent et al (1957) which suggest, in fact, that the prophage and the resting phage particle contain identical amounts of DNA, as determined by sensitivity to decay of incorporated radiophosphorus.

Lysogenization. When a sensitive bacterial culture is infected with a temperate phage, some of the cells lyse, and some of them multiply to yield lysogenic clones The fre-

quency of lysogenization often depends on the physiologic state of the bacteria before infection, on the multiplicity of infection, and on experimental treatments applied after infection. In particular, lowering the temperature (G. Bertani, 1953) or inhibiting protein synthesis (L. E. Bertani, 1957) during a critical period following infection causes many of the bacteria that otherwise would lyse to survive and yield lysogenic descendents. However, the initially infected bacterium does not become lysogenic; it multiplies to produce a number of cells, including some that lyse, some that are uninfected, and one or more that initiate stable lysogenic clones (Lieb, 1953). These facts show that the alternative to prompt lysis is a prelysogenic state during which the material from the infecting phage particle remains multipotent and behaves neither as vegetative phage nor as prophage. Perhaps it fails to multiply but has not yet become attached to the bacterial chromosome. However, it is clear that it does not long remain inert, because sensitivity to decay of constituent radiophosphorus is lost within 20 minutes, both in cells that are going to lyse and in those to become lysogenic (Stent and Fuerst, 1956). This suggests that very little of the DNA of the infecting phage is incorporated into the prophage to which it eventually gives rise. On the contrary, the DNA "primer" seems to have carried out all its radiosensitive functions soon after infection, whatever the consequences of the infection may be.

Immunity. From the facts just given, it appears that lysogenization, and hence the temperate character, depends first of all on some frequent early failure in the lytic cycle of phage growth. In a *Salmonella* phage, at least, this can be attributed to the early production of an active immunity, not to an intrinsically feeble capacity to initiate vegetative reproduction (reviewed by Hershey, 1957a).

Once lysogeny is established, a very solid immunity to the carried phage is evident. Lysogenic bacteria seldom lyse spontaneously; they do not lyse when reinfected with the phage they carry or with many of its relatives, nor do they as a rule become doubly lysogenic when similarly reinfected.

It is plausible to attribute the immunity against double lysogenization to steric factors; if there is a characteristic site for each prophage a duplicate should be forbidden (Lwoff, 1953). The immunity to lytic development may also be related in some way to the prophage site. Jacob and Wollman (1957) analyzed 14 temperate phages selected for their failure to show cross immunity. All of them proved to occupy different prophage sites in *E. coli* K12. This could mean either that immunity to lytic development has a steric basis (Lwoff, 1953) or that highly specific immune substances are involved (Bertani, 1956).

Induction. Exposure of some lysogenic bacteria to ultraviolet light sets in train the lytic cycle of phage growth in all or most of the cells. At the same time the immunity to superinfection is abolished. Evidently, the inducing agent lifts the immunity in both senses. The phenomenon is called induction and is reviewed by Jacob and Wollman (1953).

In a single species of bacterium, some prophages are inducible, and others are not. In *E. coli* K12, inducible prophages are found to occupy various sites in a cluster near the galactose fermentation markers of the bacterial chromosome. In the same bacterium, noninducible prophages occupy sites in other regions. A number of the inducible phages although occupying different prophage sites and not showing cross immunity in lysogenic bacteria, are serologically related and genetically intercrossable (Jacob and Wollman, 1957). This correlation between phage properties and prophage region is unexpected and introduces new considerations into the difficult problem of phage taxonomy.

Lysogenic Conversion. The presence of a prophage in a lysogenic culture affects bacterial properties in a variety of ways that are not always predictable. Besides the propensity toward spontaneous and induced phage production, and the prophage specific immunity, several characters associated with the lysogenic state have been described. Only two examples will be mentioned here.

Burnet (1934) had noted a constant association of certain phages with specific bacterial types in *Salmonella*. In a well-known example, lysogenization of certain bacterial species of group E1 (antigens 3, 10) with phages carried by group E2 converts the recipient bacteria into strains of group E2

(antigens 3, 15) (Uetake et al, 1955). In some instances of this type, the converted strains lose the ability to adsorb the converting phage, presumably in consequence of the antigenic change Similarly, lysogenization of appropriate strains of nontoxigenic *Corynebacterium* with phages derived from toxigenic strains produces toxigenic strains (Freeman, 1951, Groman, 1955).

In such instances there is a constant association between a specific phage and a specific bacterial property. In several instances it is currently being found that the converted trait can be recognized not only in lysogenic bacteria but also soon after infection in bacteria that are going to lyse (Barksdale, Luria, Uetake, Zinder, personal communications)

Mutations Affecting Lysogeny. Temperate phages are subject to the same classes of mutation seen in virulent phages, and the same genetic methods of analysis are applicable in both cases (Jacob and Wollman, 1955, Kaiser, 1955). In addition, there are certain types of mutation that can be recognized only in temperate phages

One class of mutations (v mutations) confers on the phage the ability to overcome the immunity to superinfection exhibited by bacteria carrying the original phage In one example of this kind, the development of the carried phage is induced by the superinfection, and a mixed yield of virulent and temperate phages results (Jacob and Wollman, 1953).

Mutations suppressing or diminishing the ability to lysogenize (c mutations) have been studied rather thoroughly in coliphage lambda (Kaiser, 1957) and in *Salmonella* phage P22 (Levine, M, 1957) with rather similar findings These mutations occur in a small region of the phage chromosome that can be subdivided into three distinct functional segments, one of which, in lambda, is also the site of v mutations. It appears that the region subject to c and v mutations overlaps with the region determining immunity patterns, which, in turn, is the region controlling the site of prophage localization in the bacterium (Kaiser; see Jacob and Wollman, 1957). This confirms that ability to lysogenize is indeed tied up with mechanisms of immunity production and prophage attachment to the bacterial chromosome and illustrates once more the genetic analysis of complex functions.

Mutations toward virulence (c mutations) are common and occur at multiple chromosome sites which form clusters in the phage chromosome. The reverse mutations are rare and all but unknown. According to the hypothesis of Streisinger and Franklin (1956), this tends to justify the view already expressed that temperateness in phages is a "positive" character and that virulence corresponds to a loss of function.

Defective Prophage. Another class of mutations peculiar to temperate phages gives rise to so-called *defective lysogenic bacteria* These are obtained most conveniently by exposing typical lysogenic cultures to large doses of ultraviolet light and selecting survivors that retain the characteristic immunity to phage but otherwise are apparently nonlysogenic If the original culture was inducible, the defective culture may retain this property, that is, it may lyse after the characteristic latent period following exposure to ultraviolet light, but few or no phage particles are produced.

Each defect can be traced to a definite locus on the phage chromosome and to an interruption of phage growth at some stage in the lytic cycle. In some defective cultures vegetative reproduction occurs following induction (as tested by superinfection experiments using genetically marked phages), and phage specific antigens are formed, but no morphologically intact phage particles (Jacob and Wollman, 1956) In such instances the defect resembles that observed in cultures of T2 inhibited by proflavine (DeMars, 1955)

In general, phage production is normal if the defective culture is induced (to lift the immunity) and superinfected with normal phage. Under these conditions genetic and physiologic contributions from the defective prophage can be recognized (Jacob and Wollman, 1956; Jacob et al, 1957) In certain instances, the mixed infection gives rise to morphologically intact particles carrying the genetic defect. Such particles are noninfective except that they can again establish defective lysogeny with low frequency (Appleyard, 1956). In mixed infections of this kind, the defective function is evidently made good by the nondefective phage, a phenomenon made use of in the test of functional complementarity (Benzer, 1955)

Defective lysogeny is instructive in several respects. The responsible mutations affect primarily the lytic cycle of phage growth but would pass unnoticed in virulent phages because they would be lethal. Just as a virulent phage may be regarded as one that has lost the power to lysogenize, a defective prophage corresponds to a phage that has lost the ability to complete the lytic cycle of phage growth. It functions very nearly as an ordinary determinant of bacterial heredity. Most important, mutations producing defective prophages offer a means of analyzing phage growth and morphogenesis by the usual methods of chemical genetics (Jacob et al., 1957).

Mixed Inheritance. Since the general characteristics of lysogeny began to be appreciated, the idea of genetic homology between bacterium and phage has seemed to be increasingly appropriate (Lwoff, 1953, Bertani, 1953). In its origins, this idea merely reflected the fusion of phage inheritance and bacterial inheritance seen in lysogenic bacteria. Since 1953, however, the idea has already acquired a long history of more or less useful applications (Fraser, 1957, Stent, 1958). Finally, a defective prophage has been found which seems to unite in its structure mutational markers of authentic bacterial and viral origins and can give rise to bastard phage particles. This development is described below in connection with the subject of transduction.

INFERENCES IV

The lysogenic character has been aptly described as a hereditary property of a bacterium that can be acquired by infection with a virus. Once established, it differs from other bacterial markers only by virtue of its special lethal potential, which is the price paid by the bacterium for remarkable gains in genetic versatility.

The lysogenic bacterium harbors a well-defined prophage. The main biologic affinities of the prophage are well illustrated by two classes of mutation to which it is subject. A temperate phage can lose the power to lysogenize, becoming "pure virus." A temperate phage can also lose its viral potential, becoming a defective prophage. A defective prophage is a gene cluster in a bacterium. Only a sophisticated virologist can trace its origin in a phage.

OTHER CONSEQUENCES OF INFECTION

Mixed Infection. Genetic recombination, phenotypic mixing, multiplicity reactivation and cross reactivation can be interpreted, in broad terms, as intelligible genetic interactions observed in mixed infections. These interactions occur only between related phages and have been described already. Some less intelligible consequences of mixed infection will be mentioned here.

When a bacterium is infected with two unrelated phages (differing morphologically or possessing no common antigens), one or the other, but seldom or never both, produce offspring. This phenomenon is called *mutual exclusion between unrelated phages*, and has received no satisfactory explanation (Weigle and Delbruck, 1951). It is clearly due to genetic differences between the phages and should not be confused with the immunity characterizing the lysogenic state, which obeys very different rules. However, lysogenic bacteria are refractory to infection by certain heterologous phages, and this phenomenon could be related to mutual exclusion, though it seems to be much less general (Lederberg 1957).

If mixed infection is brought about by distantly related phages, such as T2 and T4, one of the pair tends to be excluded, completely in some bacteria and partially in others. This effect is also clearly due to genetic differences between the phages. Among the progeny of crosses between T2 and T4, Streisinger and Weigle (1956) found that the ability of T4-like particles to exclude T2 is correlated with other characteristics, including high DNA-glucose content, that do not segregate as do the usual genetic markers. This type of exclusion may be characterized as *partial exclusion between distantly related phages*.

In simultaneous infection with several identical phages there is also probably a small amount of exclusion. This can be shown by mixed infection with 10 to 20 particles of T2 and 1 or 2 particles of an r mutant of T2

per bacterium Under these conditions a certain proportion of the mixedly infected cells will not yield any *r* phages, an effect which probably cannot be ascribed to the r marker itself. Dulbecco (1949a) interpreted this phenomenon as a limitation to the number (about 10 in his experiments) of particles that can participate in phage growth in one cell. However, if it is assumed that not all particles inject simultaneously, this limited participation could be only another expression of the well-defined phenomenon to be described next.

Partial exclusion of superinfecting phage is seen when bacteria are infected first with one and then with another of two very closely related phages It does not depend (except for convenience of demonstration) on genetic differences between the two phages The resistance to superinfection is demonstrable within 1 minute after infection (Dulbecco, 1949b) but probably does not become maximal for several minutes Resistance to superinfection by T2 is accompanied by resistance to lysis from without (Visconti, 1953), by reduced efficiency of injection (Hershey et al, 1954), by cyclical changes in cell premeability (Puck and Lee, 1955), and by the ability of the cells to decompose the DNA of superinfecting phage particles (Graham, 1953) The exclusion is partial in respect to all these phenomena, and some of the superinfecting particles always succeed in infecting (Visconti, 1953). All of the effects mentioned can be explained by assuming some change in the cell surface that interferes with normal injection Resistance to superinfection of this type has been studied mainly with *T2* and is less marked or absent with some other phages

Host-Controlled Variation The terms "host-controlled variation" or "host-induced modification" refer to the fact that the host-range property of phage particles is sometimes

not affect injection. It presumably reflects an alteration of some internal component of the phage particle, but of what kind is not known The phenomenon differs from typical mutation in several respects, notably by the fact that all the particles issuing from the modifying host are usually modified, independently of the state of the infecting particle. For this reason host-controlled variation is often called phenotypic or, more accurately, nonheritable Further details will be found in reviews by Luria (1953) and Adams (1958).

Transduction is a remarkable process by which factors from a genetically marked donor bacterium may be carried into an acceptor bacterium by a phage particle, modifying the bacterial inheritance (Zinder, 1955). The phenomenon has been used extensively for genetic analysis of bacteria (reviewed by Hartman, 1957) We present here only the main facts that seem to bear on the biology of phage

To begin with, one must distinguish between two kinds of transduction, seen with different phages "Typical transduction," observed with several phages, shows the following characteristics (Zinder, 1955):

1. The material carried by the phage consists of a fragment of a bacterial chromosome which effectively substitutes for a corresponding region of the chromosome of the acceptor bacterium. The fragment usually accommodates only a single bacterial marker but may include 2 or more linked markers (Lennox 1955, Jacob, 1955, Demerec and Demerec, 1956)

2 The effective material is derived exclusively from the bacterium in which the vector phage particle was produced; it shows no relation to the germ line of the phage The acceptor bacterium need not become lysogenic. Both facts distinguish typical transduction from lysogenic conversion

3 All bacterial characters that have been tested are transducible Typical transduction furnishes no clue in this respect to the presumed site occupied by the prophage in lysogenic bacteria

4. Only a small fraction (10^{-6}) of particles in a given preparation appears to be competent in the transduction of a given marker It is not known whether these particles are infective in the usual sense (Zinder, personal communication).

5. Phage particles heavily irradiated with ultraviolet light or subjected to decay of incorporated radiophosphorus, treatments effective in destroying infectivity of phage, do not destroy the transducing power of the particles (Garen and Zinder, 1955).

These facts are consistent with the idea that when a phage particle matures, bits of chromosomal material of bacterial origin can be included in it by accident According to this interpretation, transduction is only a special case of transformation of bacterial characters by DNA (Lederberg, 1955). This view suggests either that some fraction of the DNA in a phage particle is superfluous to the infective property or, if transducing particles are not infective, that the maturation process has imperfect discriminatory power toward DNA. Indeed, the discovery of transductions of lysogeny (Jacob, 1955, Lennox, 1955) suggested that there might be room in a single phage particle for intact chromosomes derived from 2 or 3 phage lines and fragments from the host as well Various reservations to this conclusion were necessary at the time, and the study of transduction by phage lambda has since shown that transducing phage particles in that system are in fact noninfective Therefore, the significance of typical transduction for questions about phage structure is not clear

Transduction observed in *E. coli* K12 by phage lambda (lambda transduction) differs from that described above in several ways The differences should be ascribed to the phage, not to the bacterium, because transduction in K12 by phage P1 is typical (Lennox 1955) Lambda transduction shows the following distinctive features (Morse et al., 1956).

1. Transducing phages are obtained in the first instance by induction of lysogenic bacteria with ultraviolet light, never by infecting sensitive bacteria

2 The cells modified by transduction always carry prophages

3 Only the galactose fermentation markers adjacent to the prophage site are transducible

4 Most of the cells modified by transduction do not arise by genetic substitution as in typical transduction but by addition of genetic material, they persistently throw off daughter cells of the acceptor type with low frequency These genetically unstable cell lines are called heterogenotes

5 Induction of phage production in heterogenotes yields phage, called HFT, transducing the galactose character with very high frequency.

The availability of HFT phage permits experimentation with a precision previously unattainable in transduction experiments Owing to this fact, the following additional information could be obtained (Weigle, 1957; Campbell, 1957, Arber et al, 1957)

6. HFT phage consists of a mixture of normal phage particles and defective particles in approximately equal numbers. The normal particles are nontransducing The defective particles adsorb to bacteria but mostly kill and lyse them without multiplying However, a few of them produce new heterogenotes, but these prove to be defective lysogens High-frequency transduction, yielding actively lysogenic heterogenotes, is produced only by mixed infection with normal particles and defective particles, the latter performing the actual transduction

7 Therefore, the actively lysogenic heterogenote is a doubly lysogenic bacterium carrying a normal prophage associated with the intact bacterial chromosome of the acceptor genotype, and a defective prophage, associated with a bacterial chromosome fragment of the donor genotype On induction, both prophages initiate phage production, the defective phage being helped out by the normal one, and a mixed yield of defective particles and normal particles results

8 When the defective phage multiplies vegetatively, which it can do only in bacteria also infected with normal phage, the bacterial chromosome fragment associated with the defective prophage multiplies too Thus, whether associated with prophage or vegetative phage, the bacterial chromosome fragment behaves like part of the defective phage chromosome

9 In crosses between genetically marked defective phage and normal phage, certain characters can be separated from the defect and recovered in live phage particles However, a segment of the defective chromosome corresponding to the host range and adjacent markers cannot be recovered in this way, nor does it function in the crosses to produce phenotypic mixing Therefore, the defect lies in the region controlling host range and may correspond to a deletion of genetic material

All this suggests that transducing phages, in the lambda system, arise not by inclusion of extra material in the phage particle but by substitution of bacterial markers for phage markers, yielding a chromosome of mixed

per bacterium Under these conditions a certain proportion of the mixedly infected cells will not yield any r phages, an effect which probably cannot be ascribed to the r marker itself Dulbecco (1949a) interpreted this phenomenon as a limitation to the number (about 10 in his experiments) of particles that can participate in phage growth in one cell. However, if it is assumed that not all particles inject simultaneously, this *limited participation* could be only another expression of the well-defined phenomenon to be described next

Partial exclusion of superinfecting phage is seen when bacteria are infected first with one and then with another of two very closely related phages It does not depend (except for convenience of demonstration) on genetic differences between the two phages The resistance to superinfection is demonstrable within 1 minute after infection (Dulbecco, 1949b) but probably does not become maximal for several minutes. Resistance to superinfection by T2 is accompanied by resistance to lysis from without (Visconti, 1953), by reduced efficiency of injection (Hershey et al, 1954), by cyclical changes in cell premeability (Puck and Lee, 1955), and by the ability of the cells to decompose the DNA of superinfecting phage particles (Graham, 1953). The exclusion is partial in respect to all these phenomena, and some of the superinfecting particles always succeed in infecting (Visconti, 1953). All of the effects mentioned can be explained by assuming some change in the cell surface that interferes with normal injection Resistance to superinfection of this type has been studied mainly with T2 and is less marked or absent with some other phages

Host-Controlled Variation. The terms "host-controlled variation" or "host-induced modification" refer to the fact that the host-... tion of phage particles is sometimes

does not affect the ability of the phage to attach to the indicator host and probably does not affect injection It presumably reflects an alteration of some internal component of the phage particle, but of what kind is not known. The phenomenon differs from typical mutation in several respects, notably by the fact that all the particles issuing from the modifying host are usually modified, independently of the state of the infecting particle. For this reason host-controlled variation is often called *phenotypic or, more accurately, nonheritable* Further details will be found in reviews by Luria (1953) and Adams (1958).

Transduction is a remarkable process by which factors from a genetically marked donor bacterium may be carried into an acceptor bacterium by a phage particle, modifying the bacterial inheritance (Zinder, 1955) The phenomenon has been used extensively for genetic analysis of bacteria (reviewed by Hartman, 1957). We present here only the main facts that seem to bear on the biology of phage.

To begin with, one must distinguish between two kinds of transduction, seen with different phages. "Typical transduction," observed with several phages, shows the following characteristics (Zinder, 1955):

1 The material carried by the phage consists of a fragment of a bacterial chromosome which effectively substitutes for a corresponding region of the chromosome of the acceptor bacterium The fragment usually accommodates only a single bacterial marker but may include 2 or more linked markers (Lennox 1955, Jacob, 1955; Demerec and Demerec, 1956)

2. The effective material is derived exclusively from the bacterium in which the vector phage particle was produced; it shows no relation to the germ line of the phage The acceptor bacterium need not become lysogenic. Both facts distinguish typical transduction from lysogenic conversion.

3 All bacterial characters that have been tested are transducible Typical transduction furnishes no clue in this respect to the presumed site occupied by the prophage in lysogenic bacteria

4 Only a small fraction (10^{-6}) of particles in a given preparation appears to be competent in the transduction of a given marker. It is not known whether these particles are infective in the usual sense (Zinder, personal communication)

5. Phage particles heavily irradiated with ultraviolet light or subjected to decay of incorporated radiophosphorus, treatments effective in destroying infectivity of phage, do not destroy the transducing power of the particles (Garen and Zinder, 1955).

origin. In any case, the process is clearly not random, the foreign material included in the phage particle is derived from the region of the bacterial chromosome adjacent to the prophage site, and its inclusion gives rise to a specific hereditary defect in phage function

INFERENCES V

In lysogeny one sees an integration of phage material and bacterial material in which the integrated unit behaves as a nearly normal *bacterial chromosome In typical transduction*, one sees a mechanism for the transfer of genetic material from one bacterial chromosome into another, in which the phage plays a purely mechanical role. In typical transduction, unlike lysogeny, there is no fusion of phage inheritance and bacterial inheritance. Transduction by phage lambda is neither transduction nor lysogeny, as understood previously. As in lysogeny, one sees an integration of genetic material from phage and bacterium, but the unit of integration is not a bacterial chromosome or a phage chromosome but something having resemblances to both On the one hand, aided by a normal phage chromosome it multiplies vegetatively and fits into a phage particle to form a characteristic biologic unit possessing many phage functions but lacking others. On the other hand, it can be perpetuated in unstable association with a normal bacterial chromosome, where it performs some bacterial functions and some prophage functions, resembling a supernumerary chromosome fragment of mixed origin.

The details of these unexpected phenomena are relevant to an eventual generalization that might read something like this: the modalities by which chromosomes express their presumed basic attributes are indefinitely various because history has presented genetic materials with innumerable opportunities. *It follows from this generalization that every genuinely new method of looking at living things must reveal unexpected phenomena, and it is only by cultivating his astonishment that the observer can hope to achieve a grasp of the presumed basic attributes. Perhaps the first* main point to emerge from the study of temperate phages is that phage heredity and bacterial heredity are interwoven quite as closely as are phage and bacterial functions; then the second main point would be that the interweaving is not inextricable.

The role of DNA as the material basis of heredity in phages and bacteria, though now factually clear, does not yet lend itself to generalization owing to the growing evidence that other viruses, and perhaps phages too at some time in their life cycle, can dispense with DNA The existence of "DNA viruses" and "RNA viruses," for the present, merely raises questions that escape us Do, for instance, viruses and their hosts generally form com*mon reservoirs of genetic material or is this* a corner of DNA history to which only certain phages and bacteria have access?

Chick-Embryo Technics

INTRODUCTION

For centuries the developing chick embryo has attracted a wide range of interest in medical and biologic research Since 1931 much progress has been made in its adaptation for the propagation of infectious agents and for the study of the diseases they produce. The embryonated hen's egg has been found to be particularly well suited for many of the viruses and most of the rickettsiae known to be pathogenic for man and animals Under proper conditions experimental infections provoke typical disease reactions in the embryo Therefore, it is one of the most useful laboratory animals for the study of the pathogenesis of infectious diseases and the analysis of many factors related to immunity.

Isolation and identification of the causative agent by inoculation of chick embryos is now standard procedure for many viral and rickettsial diseases Large quantity production from infected chick embryos has furthered much knowledge regarding the physical, chemical and many other basic properties of several viruses Assembly line procedures have been developed for the preparation of vaccines from this source Important diagnostic antigens are obtained by the chick embryo method The biologic assay of many therapeutic agents is carried out by this means

HISTORY

The general use of the chick embryo for the study and the propagation of infectious agents began to develop after Woodruff and Goodpasture (1931) described infection of the chorio-allantoic membrane with fowlpox virus. Later in the same year they reported with Buddingh (1931) that the viruses of vaccinia and herpes simplex also could be propagated by this method A successful smallpox vaccine prepared from infected chorio-allantoic membranes was reported almost simultaneously by Goodpasture and Buddingh (1933) and by Stevenson and Butler (1933) from England. These experiences prompted Goodpasture (1933) to emphasize the potentialities of the chick-embryo method for most of the purposes to which it has been adapted since then He and his associates explored many of its uses for the study of viral and bacterial infections and provided the basis for many of its practical applications

Beginning in 1933, Burnet and his collaborators contributed much to the advance of the new technic Their efforts were particularly significant in devising means for utilizing the chick embryo for quantitative studies The lethal effect of fowl plague and Newcastle disease viruses on the embryo was

wider surface area This made the pock-counting technic feasible by means of which quantitative studies with vaccinia, herpes simplex, ectromelia and their specific antibodies were undertaken

munization imposed by World War II greatly accelerated development of the chick-embryo method for the production of yellow fever, typhus, influenza and other vaccines

Before 1931, several experiments presaged the eventual use of the chick embryo for these purposes. Thus, Rous and Murphy (1911) propagated and studied the effect of the agent of chicken sarcoma in the developing egg Jouan and Staub (1920) propagated fowl-pest virus by this means Gay and Thompson (1929) described an increase of vaccinia virus introduced into the yolk sac of chick embryos Goodpasture (1938) quotes Levaditi (1906) to indicate that Borrel perhaps was the first to use the developing egg for the study of infection In 1904 Borrel studied spirillosis of fowls after inoculation of fertile and unfertile incubating eggs More detailed accounts of the history of the development of the method are available in Burnet (1936), Goodpasture (1938), Beveridge and Burnet (1946) and Burnet (1953)

GENERAL CONSIDERATIONS

The basic chick-embryo technics are now standard methods The publications of Goodpasture and Buddingh (1935), Burnet (1936), Polk et al (1938) Beveridge and Burnet (1946) and Buddingh (1953) as well as several recent textbooks and manuals can be consulted for descriptions of the essential procedures One of the outstanding features of the method is its versatility in that different routes of inoculation are practicable Thus the chorio-allantoic membrane, the allantoic cavity, the amniotic cavity, the yolk sac, the veins of the membranes and the embryo itself are accessible as sites in which infection can be established Each of these routes of inoculation is best suited to a definite purpose with a particular virus or rickettsia Differences in the performance of details in various procedures have been developed by many investigators to suit the needs of particular research problems Diagnostic laboratories have introduced adaptations which facilitate their work Pharmaceutical establishments interested in large quantities have placed the embryonated egg on the assembly line for the commercial production of vaccines and diagnostic reagents

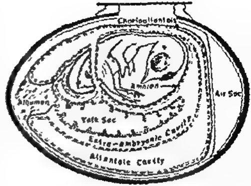

FIG 44 Diagram of embryonated egg of 11 days' incubation showing the important structures involved in the chick-embryo technics

As discussed elsewhere (Buddingh, 1950, 1952a, b) embryonated eggs should not be compared with tubes of nutrient media primarily useful for the propagation of microorganisms Each is a complete self-sustaining laboratory animal which in the short space of 21 days progresses from the fertile egg to the hatched chick This series of changes provides a variety of biologic subtrates to which viruses and rickettsiae are variously adapted The cells of the different tissues and organs of the embryo and of the extra-embryonic structures which support the replication or multiplication of these agents maintain a metabolism in which certain processes predominate during definite stages of incubation These in turn may markedly influence the behavior of the infectious agent and the reaction of the embryonic host During the first 10 days of incubation the metabolic processes from which energy is derived consist mainly of the combustion of carbohydrates, especially glucose, derived from the albumen All types and varieties of cells appear to share in these metabolic processes During this period cellular proliferation and metabolism proceed at their highest rates of activity Extreme and uniform susceptibility with rapid rate of viral proliferation characterizes the 6- to 10-day embryo It is at this stage that the virus-infected embryonated egg perhaps most nearly resembles a test tube culture of bacteria

From the 10th to the 15th day of incubation there is a slowing down of embryonic metabolism. The catabolism of proteins rather

* Adapted from Cox (1952), Growth of viruses and rickettsiae in the developing chick embryo Ann New York Acad of Sc, 52, 236-247

The experiments of Wilson Smith (1935) marked the beginning of an immense amount of research on the behavior of influenza virus in embryonated eggs This work has been shared by many laboratories in all parts of the world The resulting harvest of informa- [illegible] ference and recombination phenomena of influenza virus has greatly enriched the science of virology.

Zia (1934) in Zinsser's laboratory first cultivated the rickettsiae of murine typhus and of spotted fever in the chorio-allantois Cox (1938) demonstrated the superiority of the yolk sac for the purpose of propagating these agents The demands for mass im-

avian lymphomatosis and possibly ornithosis As pointed out by Cox (1952), endogenous infections have presented no appreciable problem in experimental work or in the production of vaccines

The Inoculum: Fungi, bacteria and viruses may be present as contaminants in the inoculum. Their effect will vary with the age of the embryo and with the route of inoculation Embryonated eggs of less than 11 days incubation are extremely susceptible to contaminants of any type Proteolytic spore-bearing gram-positive bacilli can wreak havoc at any stage. In older embryos the yolk sac more than any other site is vulnerable to the introduction of bacteria The chorio-allantois of embryos 13 days and older will tolerate a surprising variety and number of potentially pathogenic bacteria So-called saprophytic varieties ordinarily do not thrive on the membrane Most contaminating fungi are derived from the egg shell

Bacterial contaminants are usually controlled effectively with penicillin and streptomycin added to the inoculum Fungi are much more difficult to eradicate, although mycostatin is often effective Slow-growing bacteria such as diphtheroids, certain types of micrococci and pleuropneumonialike organisms may be maintained inadvertently in serial passage with viruses under study. Their detection is sometimes difficult, and their presence may be the cause of reactions not attributable to the virus Nasopharyngeal washings and stool suspensions may carry herpes simplex virus Influenza and mumps may be encountered in throat washings in which other viruses are sought This happens very rarely and is of slight practical importance. The time-tested and reliable methods of filtration or isolation in particular tissues of susceptible hosts preliminary to propagation in chick embryos are in many instances of greatest value Adequate bacteriologic control and careful attention to details of technic are the best prevention against contamination.

TECHNICS OF INOCULATION

Chorio-Allantoic Membrane Inoculation

The chorio-allantoic membrane is best suited for the study of viral infections characterized by focal or pocklike lesions Of those infectious for man vaccinia, variola, herpes simplex and Newcastle disease viruses produce grossly visible pocks in the membrane. Several others, including influenza A and B, are inconsistent in this respect (Cox, 1952). The cytotropisms which typify these viruses are exhibited by their effect on each of the three germinal layers of which the chorio-allantoic membrane is composed

The outer ectoderm consists of chorionic epithelium derived from the early dorsal somatopleure The inner entoderm lines the rapidly expanding allantois which originates as a diverticulum of the embryonic hind gut The middle layer represents a fusion of chorionic and allantoic mesoderm It contains the membranal arterioles venules and their accompanying lymphatics An abundant capillary plexus develops in the chorionic mesoderm During the last week of incubation the membrane serves as a respiratory organ By the 14th or 15th day capillary loops from the chorionic plexus extend into the outer ectoderm in close proximity to the shell membrane (Romanoff, 1952) Exchange of gases takes place across these structures

Embryonated eggs of 10 to 12 days incubation are most satisfactory for chorio-allantoic membrane inoculation The inoculum is introduced on the membranal surface It may be exposed by the window method as originally described by Goodpasture and Buddingh (1935) A modification which creates an artificial air space was devised by Burnet (1936) Sealing the window by means of a cover glass resting on a ring of petrolatum-paraffin mixture or by replacing the shell sector is too time-consuming if transparent cellophane adhesive tape is available. A window is not essential if the area of the membrane to be inoculated is separated from the shell by gentle suction applied to a small drill hole over the air sac. A drill hole in the shell, including a slit in the shell membrane over the area to be inoculated, must be present in order to create the artificial air sac This opening also serves for the introduction of the inoculum which then may be distributed evenly by gently tilting the egg from side to side Good transillumination of the egg in a darkened room is required for this procedure Injections can also be forced blindly between the shell membrane

than carbohydrates provides the chief source of energy During this period tissue and organ differentiation and maturation progress rapidly Infectious agents introduced at this stage proliferate at ■ slower rate Inflammation becomes more intense, and the specific localizations of typical lesions which characterize the infection in the more mature natural host become apparent This is particularly marked from the 13th through the 15th days of incubation In what manner the more efficient utilization of energy and the accentuation of metabolic processes concerned with protein synthesis promotes these more specific and mature responses is not clear It is of particular interest that these phenomena become more apparent after the 12th or 13th day when the remaining egg albumen is absorbed into the amniotic cavity.

From the 15th day of incubation until hatching the cells of the yolk sac membrane become particularly active The mobilization and transport of fat from the yolk to the embryo constitutes one of the chief metabolic activities during this period It presumably anticipates the energy demands of hatching and the first few days of the life of the chick. The final stages of incubation are marked by an increasing insusceptibility to infectious agents not naturally pathogenic for the species

Throughout incubation the embryo appears to remain immunologically inactive Nonspecific factors such as complement begin to make their appearance about the 19th or 20th day. Specific antibodies in response to infection or following the introduction of antigens have not been detected by available methods Passive transfer of antibodies from actively immunized hens to the egg has been demonstrated repeatedly Thus, diphtheria antitoxin is concentrated in the yolk of eggs from hens actively immunized with diphtheria toxoid. Embryos developing in such eggs are protected against the action of the toxin. The transfer of bacterial and viral antibodies has also been shown to take place when laying hens recover from some infections or following certain vaccination procedures It is of interest to note that when poultry feeds containing antibiotics such as chlortetracycline, oxytetracycline and chloramphenicol are included in the diet of laying hens there results an increasing resistance of the eggs to infection with rickettsiae (Grieff and Pinkerton, 1951).

Propagation in the various substrates which characterize successive stages in the development of the embryonated egg has different effects on different viruses Adaptation may be achieved within a few passages or may require blind passage through several transfers. Diminution or loss of virulence for the natural host develops at varying rates Influenza virus, for instance, changes from the O to the D phase during a few passages and quickly loses its disease-producing capacity for man without much substantial change in its antigenic qualities. Vaccinia, on the other hand, remains relatively stable and becomes avirulent for human beings only after numerour transfers in the chorio-allantoic membrane. Strains of herpes simplex have been found to vary greatly in these respects In general, continued propagation exerts an attenuating influence on viruses for the natural host while it often increases their virulence for the chick embryo Other perhaps less immediately important variations are also induced. Most of these are considered to be the result of selective survival rather than due to true mutations Since viral replication involves the intracellular assembly of essential constituents it is not surprising that the resulting infectious agent soon or late develops new characteristics. These factors must be considered in relation to problems of antigenicity, serologic relationships, virulence and perhaps morphologic and chemical attributes of viruses adapted to the chick embryo by prolonged propagation.

THE CONTROL OF CONTAMINANTS

Endogenous Infections of the Egg. The most common bacteria transmitted congenitally through the egg are *S pullorum*, the cause of white diarrhea of chicks, and *S gallinarum*, of fowl typhoid Avian tuberculosis is also known to be transmissible in this way. These infections are unlikely to be a source of difficulty because of rigid inspection and control of flocks certified for breeding The potential danger of endogenous viruses has been reviewed by Cottral (1952). These include avian encephalitis, Newcastle disease,

avian lymphomatosis and possibly ornithosis. As pointed out by Cox (1952), endogenous infections have presented no appreciable problem in experimental work or in the production of vaccines.

The Inoculum: Fungi, bacteria and viruses may be present as contaminants in the inoculum Their effect will vary with the age of the embryo and with the route of inoculation Embryonated eggs of less than 11 days incubation are extremely susceptible to contaminants of any type Proteolytic spore-bearing gram-positive bacilli can wreak havoc at any stage. In older embryos the yolk sac more than any other site is vulnerable to the introduction of bacteria The chorio-allantois of embryos 13 days and older will tolerate a surprising variety and number of potentially pathogenic bacteria So-called saprophytic varieties ordinarily do not thrive on the membrane Most contaminating fungi are derived from the egg shell

Bacterial contaminants are usually controlled effectively with penicillin and streptomycin added to the inoculum. Fungi are much more difficult to eradicate, although mycostatin is often effective Slow-growing bacteria such as diphtheroids, certain types of micrococci and pleuropneumonialike organisms may be maintained inadvertently in serial passage with viruses under study Their detection is sometimes difficult, and their presence may be the cause of reactions not attributable to the virus Nasopharyngeal washings and stool suspensions may carry herpes simplex virus Influenza and mumps may be encountered in throat washings in which other viruses are sought This happens very rarely and is of slight practical importance The time-tested and reliable methods of filtration or isolation in particular tissues of susceptible hosts preliminary to propagation in chick embryos are in many instances of greatest value Adequate bacteriologic control and careful attention to details of technic are the best prevention against contamination

TECHNICS OF INOCULATION

Chorio-Allantoic Membrane Inoculation

The chorio-allantoic membrane is best suited for the study of viral infections characterized by focal or pocklike lesions Of those infectious for man vaccinia, variola, herpes simplex and Newcastle disease viruses produce grossly visible pocks in the membrane Several others, including influenza A and B, are inconsistent in this respect (Cox, 1952). The cytotropisms which typify these viruses are exhibited by their effect on each of the three germinal layers of which the chorio-allantoic membrane is composed.

The outer ectoderm consists of chorionic epithelium derived from the early dorsal somatopleure. The inner entoderm lines the rapidly expanding allantois which originates as a diverticulum of the embryonic hind gut The middle layer represents a fusion of chorionic and allantoic mesoderm It contains the membranal arterioles, venules and their accompanying lymphatics An abundant capillary plexus develops in the chorionic mesoderm During the last week of incubation the membrane serves as a respiratory organ. By the 14th or 15th day capillary loops from the chorionic plexus extend into the outer ectoderm in close proximity to the shell membrane (Romanoff, 1952) Exchange of gases takes place across these structures

Embryonated eggs of 10 to 12 days incubation are most satisfactory for chorio-allantoic membrane inoculation The inoculum is introduced on the membranal surface It may be exposed by the window method as originally described by Goodpasture and Buddingh (1935) A modification which creates an artificial air space was devised by Burnet (1936) Sealing the window by means of a cover glass resting on a ring of petrolatum-paraffin mixture or by replacing the shell sector is too time-consuming if transparent cellophane adhesive tape is available A window is not essential if the area of the membrane to be inoculated is separated from the shell by gentle suction applied to a small drill hole over the air sac A drill hole in the shell, including a slit in the shell membrane over the area to be inoculated, must be present in order to create the artificial air sac This opening also serves for the introduction of the inoculum which then may be distributed evenly by gently tilting the egg from side to side Good transillumination of the egg in a darkened room is required for this procedure Injections can also be forced blindly between the shell membrane

and the chorio-allantois through a small drill hole Uncertain results may be expected because of the ease with which the chorio-allantois is penetrated or torn. Melted paraffin or clear nail polish effectively seals the drill holes in the shell.

The ability to distinguish between specific and nonspecific lesions is acquired by experience gained from gross and microscopic comparisons of infected membranes with membranes receiving noninfectious control inocula. Slight injuries and hemorrhages caused by manipulative procedures give rise to most nonspecific lesions They usually are situated along the course of blood vessels and are irregular in outline and distribution Careful scrutiny reveals their mesodermal localization. Microscopically, they are composed of fibroblasts and histiocytes rather than inflammatory exudate. Particles of foreign or dead tissue in the inoculum may provoke nonspecific edema and inflammation Keratinization of the ectoderm evidenced by scaliness, wrinkling and focal thickening can be mistaken for specific reactions

Lesions due to infection are usually present in considerable numbers and are uniform in distribution and appearance In most instances they appear as definite blisters or pocks representing focal proliferations of ectodermal cells In later stages they become surrounded by inflammatory exudate and show central ulceration Areas of necrosis and hemorrhage are usually indicative of active infection

The microscopic features which characterize the early stages of infection provide the best indication of the specificity of membranal lesions. Reaction in the form of cellular hyperplasia, hypertrophy, vacuolar degeneration and necrosis confined predominately to one or another of the membranal layers is in many instances typical The recognition of intracytoplasmic or intranuclear inclusions within parasitized cells is helpful in determining the specific nature of lesions caused by several viruses Subinoculation with the production of typical reactions to infection in other species is often required for identification. Final characterization is established by neutralization of a virus by its specific antiserum or by means of other appropriate serologic reactions.

Allantoic Cavity Inoculation

The allantoic cavity is enclosed by the chorio-allantoic membrane It is lined by entodermal epithelial cells which support the replication of several important viruses Inoculation of the allantoic cavity is the method of choice for the study and the propagation of influenza virus types, A, B and D, mumps virus and Newcastle disease virus Cabasso et al. (1952) have adapted poliovirus type II to propagation in the embryo by this route The various products of the process of viral replication are shed into the allantoic fluid It has been estimated by various methods (Henle, 1953) that approximately 10^{7} entodermal cells line the allantoic cavity of the 11- to 12-day embryonated egg This has provided a valuable numerical basis for quantitative studies on the replication of influenza virus and the more exact delineation of its growth curve.

The allantoic sac serves as a repository for excreta from the embryonic kidneys (Romanoff, 1952). The fluid it contains is composed of a secretion from the entodermal lining to which the kidney excreta are constantly added. Its volume increases rapidly from about 1 ml on the 7th to 5 to 10 ml by the 13th incubation day. It then rapidly decreases and has almost completely disappeared at the time of hatching Allantoic fluid contains a high concentration of uric acid Between the 11th and the 13th days a rapid increase in the concentration of phosphates takes place At lower than incubator temperatures, the phosphates precipitate as urates giving the fluid a milky appearance

Inoculation of the allantoic cavity is easily accomplished by means of syringe and needle through a small drill hole in the shell. Removal of the fluid presents few difficulties and can be achieved by a number of different methods Influenza virus is readily propagated in this way in 10- to 12-day embryonated eggs. Allantoic fluid from infected eggs has been the source material for the preparation of specimens for morphologic studies, for chemical and physical determinations and for antigenic analyses of influenza virus Most of what is known regarding the mechanisms and the practical application of the hemagglutination phenomenon has been derived from studies with virus in or derived from allantoic fluid

The effect of hormones and of various therapeutic agents has been determined mostly by the allantoic route Influenza, mumps and Newcastle disease vaccines are prepared from allantoic fluid from embryonated eggs infected with the desired virus.

De-embryonated Eggs: The de-embryonated egg technic as introduced by Bernkopf (1949) represents a special adaptation of the use of the allantoic cavity By proper manipulation the embryo and the yolk sac are carefully poured out through a wide opening made in the air sac end of the egg The connections with the chorio-allantois are severed, leaving the membrane lining the inside of the egg shell. All remaining yolk, albumen and blood are thoroughly washed out with 3 changes of cold saline. The egg contents are replaced with 10 to 40 ml of Tyrode's or other suitable solution containing antibiotics in proper amounts. A sterile rubber cap seals the opening over the air sac The chorio-allantois will survive for several days under these conditions This method has proved to be extremely valuable for controlled studies of problems regarding details of the replication and growth curve of influenza virus (Henle, 1953)

Amniotic Cavity Inoculation

A variety of cells and tissues are accessible for infection by this route of inoculation The amniotic fluid brings infectious agents into contact with the epithelial cells of the inner lining of the amnion and the epidermal epithelium of the embryo In embryos older than 12 days localization of typical lesions and inflammatory reactions are likely to develop in different parts of the respiratory and the alimentary tracts because respiratory and swallowing movements carry amniotic fluid into these areas. Herpes simplex (Anderson, 1940), influenza virus (Burnet, 1940) and several bacterial infections such as *H pertussis, H influenzae, N meningitides* and *C diphtheriae* (Buddingh, 1952b) have been studied in this manner

The amniotic route of inoculation is the method of choice for the primary isolation of all types of influenza virus Once established at this site, most strains except those of type C are readily adapted to propagation by the allantoic route Burnet (1951) regards amniotic cavity inoculation as being of greatest importance for the study of influenza virus genetics and for its maintenance in the original or O phase

The amnion develops with the chorion from the ventral somatopleure. It envelops the embryo and joins over its posterior aspect The two folds of the membrane separate except at the line of fusion. The outer fold develops into the chorion, the inner becomes the amnion The line of fusion or sero-amniotic raphe develops a lumen about the 11th day This forms the pathway along which the remaining albumen enters the amniotic fluid about the 12th or 13th day Amniotic fluid appears soon after the membrane forms It gradually increases in amount to a maximum of 3 to [illegible] ml on the 13th and then diminishes rapidly after the 16th day

The fluid-filled amniotic sac functions as a protective shock absorber for the embryo The membrane is supplied with bands of smooth muscle which are in more or less constant contraction from the 4th through the 12th days, after which they gradually slow down This activity keeps the embryo in gentle motion and tends to prevent the formation of adhesions and other abnormalities Amniotic fluid attains its maximum specific gravity and greatest protein content following the entry of the albumen on the 13th or 14th day.

This route of inoculation has many potentialities which have not been adequately explored for the study of the pathogenesis of respiratory and alimentary tract infections Combined viral and bacterial infections established in the embryo by amniotic cavity inoculation have been studied recently (Buddingh, 1956) Amniotic fluid collected from 11- to 12-day embryos infected with herpes simplex virus by the yolk sac route on the 8th day provides an excellent source of virus for serologic and other studies This method may be applied with good effect to other viruses

Inoculation of the amniotic cavity is best accomplished through a window in the egg shell In this manner the course of the injecting needle can be controlled visually and the inoculum introduced into the cavity with certainty The pre-embryonic stab method performed through a small drill hole under strong transillumination is also effective but less

reliable. Blind stabs in the direction of the embryo are not to be depended on for proper inoculation by this route

Collection of the amniotic fluid is perhaps the most difficult of all of the chick-embryo technics Familiarity with the location and the characteristics of the surrounding amnion is required. The features which distinguish amniotic from allantoic fluid at different incubation stages must be recognized Before the 12th or 13th day amniotic fluid is water clear; after this the entry of the albumen gives it a slightly yellow color and viscid consistency. After the 11th day allantoic fluid may be distinguished by the presence of precipitated urates Amniotic fluid is best obtained by aspiration with a Pasteur pipette to which slight suction is applied Careful manipulation of the surrounding membranes with sterile forceps to prevent obstruction of the pipette is often necessary. This procedure requires considerable practice.

Yolk-Sac Inoculation

Inoculation into the yolk sac is in many ways the most satisfactory of all the chick-embryo technics The cells of the yolk sac are susceptible to all viruses which can be propagated in the embryo As first demonstrated by Cox (1938), it is especially useful for growing all types of rickettsiae The MEF1 strain of type II poliovirus has been adapted to chick-embryo propagation following yolk-sac inoculation by Roca-Garcia, Moyer and Cox (1952). This was achieved after the strain had been carried through numerous passages in suckling hamsters. Brueck and Buddingh (1951) found that the yolk sac was well suited to the culture of most pathogenic fungi. It has been used with good results for the propagation of many of the African and South American arthropod-borne viruses

The infected yolk sac is used for the preparation of rickettsial diagnostic antigens and for those of the psittacosis-lymphogranuloma group It serves as a practical means for the production of vaccines against epidemic and murine typhus, Rocky Mountain spotted fever, Q fever, equine encephalitis, Japanese B encephalitis and rabies. Infectivity titrations, the measurement of antibody content in serum and many therapeutic assays can be performed in the yolk sac (Cox, 1952).

The yolk sac develops from the extra-embryonic splanchnopleure as a continuation of the embryonic intestine and is the earliest extra-embryonic membrane. Its growth is extremely rapid, so that it encloses the entire yolk by the 6th day. A complex circulatory system develops from hemangioblasts at a very early stage. These form spaces which coalesce into vessels containing blood plasma and the true blood islands. Erythroblasts appear on the 2nd day, and white blood cells on the 3rd day. The yolk sac functions as a blood-forming organ and in the absorption of nutritive materials from the yolk and their transport to the embryo. Secretion of enzymes by the entodermal cells of the sac liquify the yolk and participate in its digestion

Variations in the type and the rate of metabolic activities of the yolk sac cells during different stages of incubation appear to influence susceptibility to viruses and the rate of their production This is evident from Crawley's (1948) studies on the comparison of LD50 mortality end points following yolk-sac inoculation with equine encephalitis virus on the 8th day and on the 15th day of incubation.

Removal of infected yolk sacs may be accomplished by any of several methods The sac may be grasped with sterile forceps through a wide opening over the air sac end of the shell The embryo may first be removed and the entire yolk poured out Excess yolk may be drained off, leaving the yolk sac membrane which may then be minced, ground, shaken with glass beads or broken up by other means whereby suspensions or preparations of the infectious agent are obtained Thin smears stained by the Giemsa or the Macchiavello method are helpful in the detection and the identification of rickettsiae. Special procedures are involved in the large-scale production of commercial vaccines.

Embryo Inoculation

Direct injection of the embryo by means of needle and syringe or through intravenous inoculation has been used for special purposes Intracerebral inoculation with direct visualization of the embryo through a window in the shell has been found to be applicable to the study of herpes simplex (Anderson, 1940) and rabies (Dawson, 1941). This route is

not essential for the propagation of these viruses, each of which is infectious by any route of inoculation. Injection into accessible areas of the embryo such as the eye, the nose, the peritoneal cavity or elsewhere is possible but for most purposes is unnecessary The embryonic stab method is useful for the introduction of yellow fever, Japanese B and equine encephalitis viruses This injection is performed under good transillumination, using a long needle by means of which the embryo can be penetrated

Several modifications of the original method of intravenous inoculation (Polk et al, 1938) have been developed Each was devised for special purposes. Intravenous injection is not widely used but has provided information regarding the dissemination of infectious agents introduced directly into the blood It has also been used to measure the effect of antiserum and chemotherapeutic agents

Under certain conditions dead embryos can be used to propagate influenza virus Lahelle and Horsfall (1949) demonstrated this with embryos killed by storage at room temperature for 7 to 10 days or at 4° C for 4 days Propagation of the virus was achieved at 35° C for 4 to 11 days after the embryos were killed Embryos frozen at −30° C for 20 hours were found to be unsuitable for this purpose Cox (1952) observed that a greater yield of spotted fever rickettsiae was obtained from a combination of living and dead embryos Seven-day embryos inoculated in the yolk sac usually die within 3 to 4 days The rickettsiae are found in abundance in the yolk sac but are few in number in the chorio-allantoic membrane. Further incubation for 2 to 4 days at 20° to 22° C will bring about a marked increase of rickettsial growth in the membrane. Only the rickettsiae of the spotted fever group behave in this manner, those of Q fever, typhus and scrub typhus do not

Foreign Tissue Grafts on the Chorio-Allantois

Human skin grafts obtained under aseptic conditions were first maintained on the chorioallantois by Goodpasture et al (1938). Human fetal membrane split into its component chorion and amnion were shown by Goodpasture and Anderson (1942) to take readily and to be susceptible to infection with several viruses The use of penicillin and streptomycin has greatly simplified these procedures by controlling most bacterial contaminants Human foreskin and other tissues can also be utilized Li et al (1955) have used this technic recently in attempts to adapt poliovirus strains to propagation in the tissues of the embryonated egg

Use of Eggs from Other Species

Because they are so readily available, domestic hen eggs are used almost exclusively for the propagation of viruses and rickettsiae The longer incubation period of 28 days gives duck and turkey eggs an advantage over the 21 days of the hen's egg for agents which proliferate slowly For this reason Peck et al (1955) have found duck eggs to be superior for the propagation of the virus in the production of rabies vaccine Species differences have been noted by Brandly (1937) in that the virus of infectious laryngotracheitis of fowls would propagate in embryonated hen and turkey eggs but not in those of ducks, guinea fowl or pigeons. Harris (1945) described infection of turtle eggs with vaccinia virus

Tissue-Culture Technics Employed in the Propagation of Viruses and Rickettsiae

It is not surprising that attempts to propagate animal viruses and rickettsiae in isolated systems of cells followed the development by Harrison, 1907, of a simple method of tissue culture For it was early apparent to most observers that these agents, unlike bacteria, fail to multiply in lifeless media The possibilities of this new technic for their cultivation were foreshadowed in the experiments of Steinhardt et al, 1913, who showed that the virus of vaccinia at least survived for several weeks in cultures of the corneal tissue of guinea pigs and rabbits However, they did not obtain unequivocal evidence that multiplication occurred, although their results suggested that infectivity had increased 6 to 10 times. This magnitude of increase is not sufficient to indicate multiplication Indeed, 12 years elapsed before Parker and Nye, 1925, presented data that removed any doubt regarding the capacity of viruses to multiply in cultures of tissue cells These investigators carried vaccinia virus through a series of 11 cultures of rabbit testicular tissue and found, in the last, 51,000 times as much virus as in the initial preparation Since this demonstration many viruses and rickettsiae pathogenic for man and lower animals have been maintained by serial passage in tissue culture Lists of most of the mammalian viruses reported to have been cultivated up to about 1950 will be found in the reviews of Robbins and Enders (1950), Lynn and Morgan (1954) and Sanders et al (1953). Since the beginning of the present decade, as recorded in other sections of this book, a large number of others, including agents such as those comprising the Echo and the Adenovirus groups which represent hitherto unrecognized species, have been propagated in tissue cultures Many of these have been listed by Enders (1954) and Ross and Syverton (1957)

Although in the past the method was applied effectively to the investigation of several fundamental problems relating to animal viruses, during a long period it did not appear to offer the advantages for their cultivation and study provided by the susceptible animal, since it was considered that viral increase in cell systems could be demonstrated reliably only by inoculation of appropriate animals with constituents of the culture Recently, however, the tissue culture has assumed the status of a major technic in the virus laboratory Three circumstances, at least, accounted for its present importance

The first was the general recognition by virologists about 1950 that many viruses as

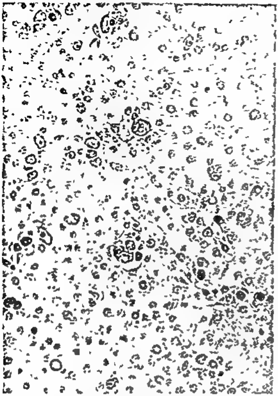

FIG 45 Primary monolayer culture on glass 37 days after trypsinized human amnion cells were placed in the tube. Trypan blue (final concentration 0 02%) was added to the culture for 10 minutes shortly before the photograph was taken. (×160)

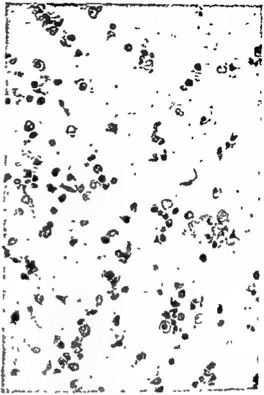

FIG 46. Appearance of human amnion cells in a culture comparable with that shown in Figure 45, 8 days after addition of 70 ID_{50} of poliovirus Type I (Mahoney strain). Note rounding, shrinking, nuclear pyknosis and disappearance of many cells (×160)

they multiply produce degenerative changes in cultured cells which can be easily distinguished This phenomenon had been described previously by a few workers (Topacio and Hyde, 1932, Huang, 1942), but its significance was not widely appreciated until about this time when it became obvious to all that with these so-called "cytopathogenic" viruses resort to the living animal was unnecessary. For, as was emphasized in the case of poliomyelitis (Robbins et al, 1950), the changes that they produce within cultured cells provide adequate criteria of their presence. Examples of these changes are illustrated by Figures 45, 46 and 47. Furthermore, it was determined contemporaneously that the addition of specific antibody to the culture along with the viral inoculum prevented the development of the cytopathic effects Accordingly, it became evident that the experimental animal could also be replaced by the culture in the demonstration and the assay of antibodies and conversely in the serologic identification of the agents themselves.

The second circumstance responsible for the present importance of the tissue culture was the development of antibiotics The inclusion of these substances in the medium made it possible to prepare and apply tissue cultures on a virtually unlimited scale. Before antibiotics were available the number and the size of cultures that could be established and maintained was greatly limited because of the necessity of exercising at every step the most stringent precautions to avoid bacterial contamination Moreover, the incorporation of antibiotics in the medium permitted the direct isolation of viruses in tissue cultures

from unfiltered fecal suspensions, throat washings and other materials heavily contaminated with bacteria

Finally, the usefulness of the method was greatly enhanced by the revival in 1952-53 of a technic devised many years earlier by Rous and Jones (1916) for the preparation of suspensions of tissue cells by treatment with trypsin From such suspensions large numbers of uniform cultures consisting of a single sheet or monolayer of cells can be prepared with great ease and uniformity

Accordingly, for many purposes both practical and investigative, tissue culture technics have supplanted those involving the use of living animals, including chick embryos, because they are more rapid, equally or more accurate and sensitive, and are applicable to a wide range of problems, some of which cannot be investigated as satisfactorily in the more complex milieu of the living animal

In this chapter the principal procedures employed in the past for the cultivation of viruses and rickettsiae in cell systems are described briefly, while those introduced during the last few years and now adopted as routine for many purposes are presented in somewhat more detail It is emphasized that the principal aim of these technical descriptions is simply to aid the reader to visualize the actual procedures so that he will be able to appreciate more readily the significance of results described in other chapters that have been obtained through the application of the tissue culture method In no sense, therefore, does this chapter represent a practical manual of tissue culture Those intending to use any of the technics outlined should consult one of the most recent treatises such as that of Melnick (1956), compiled especially for the laboratory worker, or the original articles to which references are given

TECHNICS OF TISSUE CULTURE EMPLOYED FOR THE PROPAGATION OF VIRUSES AND RICKETTSIAE

INTRODUCTION

Various procedures devised primarily for the cultivation of tissue cells have been adapted afterward to the propagation of viruses and rickettsiae In a few instances technics have also been invented with these special purposes in mind Although they differ widely in details, the essential elements of all consist of living cells and a physiologic medium for their support The original source of the cells is, of course, the tissues of the animal body Tissues for primary culture may be derived from the normal individual at any stage of development—embryonic, fetal, youthful or aged—or from neoplasms The composition of the medium may vary from a simple solution of salts and glucose to one consisting of a complicated mixture of known nutrients and accessory growth factors or one composed of tissue juices, blood serum or other body constituents in which the components are chemically undefined Depending

upon the composition of the medium, cells may survive for a time without multiplying, or they may undergo active multiplication which may continue indefinitely or cease after a while Solutions that merely permit survival are referred to as "maintenance" media; those providing factors necessary for multiplication are designated "*growth-promoting*" media

Classification of Technics

"Tissue" and "Cell" Cultures. For convenience in presentation, the various kinds of cultures employed in work with viruses and rickettsiae can be separated into two main groups (Table 8) Group I includes cell systems established with tissue fragments or with masses of cell outgrowth originating therefrom Cultures of this sort have been in use for many years Group II includes cell systems initiated with a suspension of dispersed cells As already stated, the technic for the dispersion of tissue cells was described in 1916 by Rous and Jones Long neglected, during the last few years it has become for most purposes the procedure of choice in the virus laboratory. Cultures prepared with dispersed cells have recently been termed "cell cultures" by Ross and Syverton (1957) to distinguish them from those included in Group I

The various modifications based upon these two basic procedures can be divided in each case into 2 subgroups as shown in Table 8. One comprises systems in which tissue fragments or cells are supported in or on a semisolid or solid substrate The substrate may consist of a variety of materials that include the vessel wall itself, fibrin generated from blood plasma, agar, cellophane, or cellulose strands, etc To the other belong those systems in which fragments or single cells are not fixed to a substrate but remain suspended in the nutritive medium

Procedures and Materials Commonly Employed in Tissue and Cell Cultures

As a necessary background to descriptions that follow of the different kinds of cultures mentioned in Table 8, an outline of the manner in which the tissues, the cells and other constituents in general are selected, handled or prepared is presented here.

Prevention of Contamination by Micro-organisms. Strict precautions to exclude contamination by bacteria and fungi are observed at every step. In the modern virus laboratory, as previously indicated, elimination of micro-organisms derived from the air or other sources usually is accomplished effectively by the addition of antibiotics such as penicillin, streptomycin and mycostatin to the medium. Formerly, in the prevention of airborne contamination, reliance was placed chiefly on the performance of all manipulations under conditions which reduced the bacterial content of the air to a minimum (Parker, 1950) While these measures are now not essential, their use, if facilities are available, adds a desirable factor of safety Although in most instances the antibiotics commonly employed prevent the development of micro-organisms that may be initially present in the constituents of the culture, their effectiveness cannot be taken for granted, because resistant bacteria or fungi are encountered occasionally Therefore, it is necessary to test all constituents by inoculation into suitable growth media before they are combined in the culture system

Tissues and Cells

1 Sources Tissues for primary explants are obtained from freshly killed animals, from organs removed at operation, from embryonated eggs, from embryos or fetuses taken after death of the mother or at operation, or when delivered prematurely and from fetal membranes at the time of normal delivery. At present in many laboratories stock cultures of established cell lines are maintained from which subcultures to be used for viral propagation are prepared * A few of these ... from a single

available lately, only a few have as yet been investigated extensively in respect to their reactions with a large number of viruses. Of these lines one of the oldest was developed by Earle (1943) from murine tissue and is designated the "L" strain of mouse fibroblasts Its capacity to support multiplication of various species of human viruses is limited (Scherer, 1953) A broader spectrum of susceptibility to viruses pathogenic for man is exhibited by the so-called HeLa strain (Scherer and Syverton, 1954a, 1954b, 1955), initiated by Gey and his associates (1952) from human cervical carcinoma tissue. There-

* An "established" line or strain consists of homogeneous-appearing populations of cells that have been propagated by serial explantation over a prolonged period

TABLE 8 "TISSUE" AND "CELL" CULTURE TECHNICS USED IN THE PROPAGATION OF VIRUSES AND RICKETTSIAE

Group I						Group II					
Fragments of Tissues or Cell Outgrowth						Dispersed Cells					
Suspended Fragments	Fixed Fragments or Cell Outgrowth					Suspended Cells	Fixed Cells				
	Plasma Clot		Roller Tube	Glass	Agar		Monolayer on Plasma or Glass	Monolayer on Glass and Agar Overlay	Agar	Clonal Growth	
	Drop	Flask								On Glass	On Feeder Monolayer
Maitland and Maitland (1928) Li and Rivers (1930) Plotz (1917)	Harrison (1907)	Carrel (1923)	Gey (1933)	Gey and Gey (1936) Melnick (1933)	Zinsser et al (1939)	Owens et al (1954) Earle et al (1954) Cherry and Hull (1956) McLimans et al (1957a)	Rous and Jones (1916) Lesch and Jentoft (1953) Scherer et al (1953) Youngner (1954)	Dulbecco and Vogt (1954)	Wallace and Hanks (1958)	Puck, Marcus and Cieciura (1953)	Puck and Marcus (1955)

fore, it has been adopted by many laboratories as routine for diagnostic and investigative purposes. Other available strains are the epithelial-like cells developed by Chang (1954) from different fetal tissues, those originated by Berman and his co-workers (1955) from human bone marrow and the so-called "KB," "H Ep" and "Maban" lines of human carci-

amnion and other normal human tissues, and Salk and Ward (1957) have described a line derived from monkey heart tissue

2. SELECTION OF SUSCEPTIBLE CELLS As indicated, cells derived from many animal species and from different organs have been employed in the cultivation of viruses. Embryonic cells tend to grow more rapidly and vigorously than those of more mature individuals For this reason and because they may be obtained easily, chick-embryo tissues were frequently selected by earlier workers. Because they are readily available, primary explants of the tissues of small laboratory animals such as rabbits, guinea pigs and mice were also used extensively in the past

While the cells of lower animals are still often employed in the cultivation of certain viruses, it gradually became apparent that a number of agents associated with human diseases, for example poliovirus and the agent of varicella, fail to increase in them In 1949 it was shown (Enders et al., 1949, Weller et al, 1949) that polioviruses multiply readily in cultures of different human tissues Subsequently, investigations have demonstrated the capacity of human and other primate cells to support the growth of viruses that behave in an analogous manner (cf Ross and Syver-

man Similarly, it has been emphasized lately that agents pathogenic for lower animals, e g, the virus of canine hepatitis (Fieldsteel and Emery, 1954), which do not multiply in cells of unrelated animals can be cultivated easily in those of the same species The success of contemporary researches on certain viruses of importance in veterinary medicine thus depended upon increasing recognition of this fact.

Although it is clear that marked differences are encountered in resistance of cells from different species when they are first explanted, there are indications that these differences may be obliterated after prolonged cultivation in vitro. For example, Gey and Bang (1951) found that an established line of normal rat fibroblasts was completely resistant to eastern equine encephalomyelitis virus In contrast, a strain of malignant cells derived from this normal line not only supported multiplication of the agent but was completely destroyed by it. Sheffield and Churcher (1957) have shown lately that a line of rabbit embryonic kidney cells established by Westwood and his co-workers (1957) eventually become susceptible to infection by poliovirus Therefore, it would seem possible that the susceptibility to viruses of cells of other established lines may be found occasionally to depart widely from that characteristic of the progenitors of the line.

Resistance or susceptibility of cells from the same species may also be correlated with morphologic type as demonstrated by several investigators An illustration of this fact is provided by Stulberg and Schapira (1953) who found that influenza A virus multiplied actively in epithelial cells from the chick embryo's lung. In fibroblasts from the same source no evidence of increase was obtained Furthermore, variants of the same viral species may exhibit differences in their capacity to multiply in or injure the same kind of cell (Jervis, 1955, Enders, 1957).

Because of these variations in cellular resistance it is obviously essential to select susceptible cells for the cultivation of a given virus When the nature of the virus is unknown, it is equally evident that cultures of cells of different types from the natural host or one closely related should be employed initially.

3. HANDLING OF TISSUES In the removal of tissues from the animal body or the egg, care is taken to avoid crushing and to prevent the tissue from coming in contact with chemical disinfectants or other materials injurious to cells As soon as possible after removal, the tissue is cut into fragments which are placed in a maintenance medium.

4. STORAGE. Tissue fragments or suspensions of dispersed cells, as well as completed cultures, can be stored for considerable periods under suitable conditions The latter may vary according to the nature of the material Many kinds of cells survive and are capable of subsequent multiplication after storage at 4° to

even

or 32

prolonged periods, provided that a nutrient medium is supplied While metabolic processes continue under these circumstances, cell division is greatly reduced At temperatures of $-60°$ to $-70°$ C. cells suspended in a medium containing glycerine and quickly frozen may be preserved for months (Scherer and Hoogasian, 1954).

5 Media As noted, numerous media of widely varying chemical composition have been employed to maintain the viability or promote the active multiplication of cells in culture Taken as a whole, media that merely preserve for a time cell viability and metabolism are less complex than those which provide factors essential for active and continuous cell propagation Thus, certain cells may survive for periods of several weeks in dilute mixtures of a few inorganic salts and glucose often referred to as "balanced salt solutions," although under these conditions little or no multiplication takes place The prototype of such mixtures is Tyrode's solution which has the composition given in Table 9. In tissue cultures used for the propagation of viruses it was first employed by Li and Rivers (1930) and subsequently has been modified in various ways with the purpose of increasing its efficiency as a cell-sustaining medium Balanced salt solutions of the composition devised by Earle (Table 9) and Hanks (Melnick, 1956) are among those now in more common use Included as routine in these simple solutions as well as in more complex media is an indicator dye, usually phenol red, which serves to detect changes in pH that are regularly brought about by metabolizing cells in closed systems When the latter are killed by viruses or other agents the pH remains constant

Occupying a position intermediate between the salt mixtures and the complete growth-promoting media are those of definite but complex chemical composition In the case of nearly all cells that have been examined, mixtures of this kind may support growth as well as preserve cell viability over varying periods Eventually, however, metabolism and growth diminish An exception is presented by a clonal line of strain L cells which Evans and her co-workers (1956) showed to be capable of continued active multiplication in a medium of defined but highly [illegible]

[illegible] addition to the components of

Table 9 Composition of Tyrode's and Earle's Salt-Glucose Solutions (aqueous) *

Constituents	Grams per Liter	
	Tyrode	Earle
NaCl	8 00	6 80
KCl	0 20	0 40
$CaCl_2$	0 20	0 20
$MgCl_2 \cdot 6H_2O$	0 10	—
$MgSO_4 \cdot 7H_2O$	—	0 20
$NaH_2PO_4 \cdot H_2O$	0 05	0 14
$NaHCO_3$	1 00	2 20
Glucose	1 00	1 00

* From Parker (1950)

Earle's solution it contains many of the biochemical factors known to be involved in cellular metabolism These include 19 amino acids, glutamine, vitamins A, D, E, K and the B group, biotin, folic acid, cholesterol, purines, pyrimidines, ribose, desoxyribose, adenylic acid, adenosinetriphosphate and ferric nitrate.

While defined media of this sort may be required, or at least may give better results with certain kinds of cells, it is apparent that with others the number of components can be much reduced For example, Rappaport (1956) consistently observed limited multiplication and prolonged survival of monkey renal cells in a mixture of inorganic salts, 5 trace elements, glucose, ribose and 7 amino acids

Under certain circumstances these media are preferable to either salt-glucose solutions or the complete growth-promoting media They may provide factors lacking in the simplest media that are essential in viral multiplication or at least greatly enhance it As compared with complete media, the absence of serum and tissue proteins is advantageous for many reasons Thus, such substances may interfere with infection of the cells by virus from infected culture fluids, impede accurate investigation of biochemical factors involved in viral synthesis and preclude their use in the manufacture of vaccines, because they may induce protein hypersensitivity or serum hepatitis in the recipient

Mixtures capable of supporting cellular multiplication indefinitely were devised soon after Harrison's development of the tissue culture. Details of the preparation of the various constituents as well as information

regarding the proportions in which these may be combined will be found in Parker's monograph (1950) Qualitatively and quantitatively, the composition of complete growth media has varied greatly, as will be evident from even a cursory glance through the references to media listed in Murray and Kopech's monumental bibliography of the literature on tissue culture (1953). All contain as an indispensible constituent animal protein or chemically ill-defined break-down products of animal protein. Accordingly, although it has been pursued long and actively, the formulation of a medium of defined chemical composition that will support continuous cell multiplication, with the exception noted above, has not yet been achieved However, the recent formulation of solutions such as those of Waymouth (1956), Healy et al. (1955), Evans and her associates (1956) and Eagle (1955b) appear to have brought us much closer to this important objective

Most of the complete media employed in the cultivation of viruses or rickettsiae have consisted essentially of blood plasma or serum or a combination of these and an extract of embryonic or adult tissue Balanced salt solution is usually added in varying proportion to these basic constituents

Fowl plasma, although representing a heterologous element in cultures of mammalian cells, usually has been selected because the fibrin clot derived from it is firmer, more transparent and more resistant to lytic enzymes produced during cell growth than those from mammalian plasma Although plasma may furnish the only source of nutritive materials, as in the plasma hanging-drop culture, in other systems it serves to attach tissue fragments to the vessel wall and provides a favorable surface for migration and growth of cells

Blood serum of mammals and birds, as long recognized, contains unknown substances requisite for the continuous growth and multiplication of most cells. Lately this fact has been strongly re-emphasized by Eagle's (1955) experiments on the amino acid and vitamin growth requirements of L strain and HeLa cells. Although Eagle showed that each of 13 amino acids and 7 vitamins were essential as well as certain other substances of definite composition, undefined factors supplied by the dialysed serum also proved to be indispensible. Whereas these factors may be found in other proteins, usually they have been supplied most conveniently in the form of blood serum. Growth of many cells will take place in media containing sera of heterologous species However, in certain cases, [illegible]

cells may be adapted to a medium containing heterologous sera. Even more rigid requirements in respect to the nature and the origin of the serum are exhibited by some cells as exemplified by Chang's (1954) experiments on the cultivation of lines of human embryonic conjunctival, renal and hepatic cells For a prolonged period following their establishment in vitro these cells proliferated actively only in sera derived from selected human donors.

Extracts of various organs of postnatal animals as well as of embryonic tissues have long been known to contain factors that stimulate the multiplication of cells in vitro. Chick-embryo extract, because of its activity and [illegible]

primary or early explants, extracts of beef embryo tissues are superior The chemical properties of the growth-promoting substances in tissue extracts are largely unknown, in spite of many attempts made to define them

Descriptions of Various Tissue Culture Technics

With this sketch in mind of the components used in various tissue cultures the technics whereby they are assembled into systems of surviving or proliferating cells are described.

Technics of Group I—Fixed Fragment Cultures. The technics included in Group I (Table 8) are considered first, beginning with those of the main subgroup in which the tissue fragments or mass of cell outgrowth are fixed to the vessel wall In 3 of these systems fixation is accomplished by means of a fibrin matrix generated from plasma Of these, 2 are now chiefly of historical interest to the virologist. Thus while the plasma or hanging-drop culture represents the prototype of the tissue culture as devised by Harrison, 1907, it offers no advantages over the more versatile roller-tube fragment culture The flask culture as developed by Carrel (1923) is to be recalled because it permitted the propagation of larger quantities of cells under conditions that could be controlled more precisely. Investigations carried out by means of the Carrel-flask culture led

to many technical improvements of importance such as the use of tissue extract to promote rapid and continuous cell multiplication. The technic of the roller tube fragment culture was perfected largely by Gey (1933) and by Lewis (1935), although the underlying principle was recognized earlier. While retaining most of the advantages of the Carrel flask, in addition it permits cultivation of large amounts of tissue which may be easily maintained and handled with the need for little equipment other than that found in any microbiologic laboratory. However, except for special purposes, it has been superseded lately by the dispersed cell culture. For complete descriptions of the plasma-drop and the Carrel-flask technics Parker's monograph (1950) should be consulted. Details of the roller-tube technic are given by Melnick (1956).

1. Plasma-Drop Cultures. In the preparation of primary explants the tissue is cut into fragments about 1 mm in the longest dimension. Then a fragment is centered in a drop of medium which previously has been placed on a coverslip and usually consists of a mixture of equal parts of fowl plasma and balanced salt solution. After the plasma coagulates, the preparation is inverted over the cavity of a depression slide. The coverslip is fixed at the edges to the slide with paraffin. The preparation may be examined under the oil-immersion lens in the fresh state, or sections may be cut after fixation and staining. Within a few days at 37° C a mass of cell outgrowth occurs about the periphery of the fragment. From this outgrowth secondary explants may be initiated by dividing it into sections and transferring each section to a plasma drop. Within a short time the cells in these "explants" increase to such an extent that further subdivision and explantation is required.

2. Carrel-Flask Cultures. Because of certain disadvantages inherent in the plasma-drop method (small amount of cells, necessity for frequent explantation, difficulty in sampling or altering the menstruum surrounding the cells), Carrel devised a system in which cells could be maintained for much longer periods without explantation. This system consists of cells, plasma coagulum, nutrient medium and an overlying gas-mixture. The culture is established in a flat-walled circular flask in which a shallow layer of medium bathes the cells which are attached by a thin layer of fibrin to one side of the vessel. Under these conditions, renewal of the medium, changes in its constituents, adjustment of pH and replacement in the gaseous phase are accomplished easily. Many studies were made of the effects on cells of changes in the fluid and gaseous phase and conversely of the effect of the latter on the growth of the cells. However, this kind of culture was never applied extensively to the propagation of viruses and rickettsiae, probably because much skill and care was required in its preparation and maintenance previous to the antibiotic era.

3. Roller-Tube Cultures. The essential constituents are the same as those included in Carrel-flask cultures. Although ordinary test tubes (150 × 15 mm) are used as routine, other vessels of various shape and size have been adopted for special purposes, such as the production of large quantities of virus. In the preparation of a roller-tube culture a drop or two of plasma is spread over the lower half of the inner surface of the tube. The tissue fragments, of which there may be 20 or more, are distributed uniformly throughout the plasma film. After the latter coagulates, about 2 ml of medium is introduced and the tube is closed with a rubber stopper. Then it is placed at a slight angle from the horizontal in a slowly rotating drum enclosed in an incubator. When the medium becomes acid it is changed. Explants can be made if required. Unless special thin-walled tubes are used, microscopic examination of the cellular outgrowth is possible only under the low-power lens. However, after fixation, embedding in collodion and staining, the entire contents of the culture can be studied in detail (Enders and Peebles 1954). This type of culture is among those well suited to investigations of the effects of prolonged association between cells and viruses, since by regulating the conditions, it is possible to preserve cell viability indefinitely.

4. Fragment Cultures on Glass and Agar. The plasma clot possesses certain disadvantages as a cell support. It tends to become cloudy as the culture ages, rendering difficult the visualization of cellular details, or it may liquefy with consequent detachment of the cells. Moreover, studies of biologic and

regarding the proportions in which these may be combined will be found in Parker's monograph (1950). Qualitatively and quantitatively, the composition of complete growth media has varied greatly, as will be evident

dispensible constituent animal protein or chemically ill-defined break-down products of animal protein. Accordingly, although it has been pursued long and actively, the formulation of a medium of defined chemical composition that will support continuous cell multiplication, with the exception noted above, has not yet been achieved. However, the recent formulation of solutions such as those of Waymouth (1956), Healy et al. (1955), Evans and her associates (1956) and Eagle (1955b) appear to have brought us much closer to this important objective.

Most of the complete media employed in the cultivation of viruses or rickettsiae have consisted essentially of blood plasma or serum or a combination of these and an extract of embryonic or adult tissue. Balanced salt solution is usually added in varying proportion to these basic constituents.

Fowl plasma, although representing a heterologous element in cultures of mammalian cells, usually has been selected because the fibrin clot derived from it is firmer, more transparent and more resistant to lytic enzymes produced during cell growth than those from mammalian plasma. Although plasma may furnish the only source of nutritive materials, as in the plasma hanging-drop culture,

long recognized, contains unknown substances requisite for the continuous growth and multiplication of most cells. Lately this fact has been strongly re-emphasized by Eagle's (1955) experiments on the amino acid and

tial as well as certain other substances of definite composition, undefined factors supplied by the dialysed serum also proved to be indispensible. Whereas these factors may be found in other proteins, usually they have been supplied most conveniently in the form of blood serum. Growth of many cells will take place in media containing sera of heterologous species. However, in certain cases,

exemplified by Chang's (1954) experiments on the cultivation of lines of human embryonic conjunctival, renal and hepatic cells. For a prolonged period following their establishment in vitro these cells proliferated actively only in sera derived from selected human donors.

Extracts of various organs of postnatal animals as well as of embryonic tissues have long been known to contain factors that stimulate the multiplication of cells in vitro. Chick-embryo extract, because of its activity and because it can be prepared easily, early came to be regarded as the standard. However, for the cultivation of some mammalian cells in primary or early explants, extracts of beef embryo tissues are superior. The chemical properties of the growth-promoting substances in tissue extracts are largely unknown, in spite of many attempts made to define them.

Descriptions of Various Tissue Culture Technics

With this sketch in mind of the components used in various tissue cultures the technics whereby they are assembled into systems of surviving or proliferating cells are described.

Technics of Group I—Fixed Fragment Cultures. The technics included in Group I (Table 8) are considered first, beginning with those of the main subgroup in which the tissue fragments or mass of cell outgrowth are fixed to the vessel wall. In 3 of these systems fixation is accomplished by means of a fibrin matrix generated from plasma. Of these, 2 are now chiefly of historical interest to the virologist. Thus while the plasma or hanging-drop culture represents the prototype of the tissue culture as devised by Harrison, 1907, it offers no advantages over the more versatile roller-tube fragment culture. The flask culture as developed by Carrel (1923) is to be recalled because it permitted the propagation of larger quantities of cells under conditions that could be controlled more precisely. Investigations carried out by means of the Carrel-flask culture led

formalinized vaccine used in the Poliomyelitis Vaccine Field Trial of 1954. Essentially the same procedures are still employed by certain manufacturers of the vaccine. To large rectangular bottles (5 liter capacity) Farrell and his associates added approximately 5 Gm. of minced kidney tissue from rhesus or cynomolgus monkeys and 500 ml. of Mixture 199. The bottles were rocked mechanically at 37° C during a period of 1 to 6 days, then the medium was removed and replaced with fresh material. Poliovirus was introduced, and agitation and incubation were continued. Within 2 to 7 days thereafter a large increase in the agent occurred as indicated by titration of the fluid phase. The low protein content of the fluid (0.25-0.30 mg. N/ml.) rendered the material especially suitable as a source of virus for the preparation of vaccine.

Technics of Group II—Fixed-Cell Cultures. The procedure devised by Rous and Jones (1916) for the preparation of dispersed suspensions of tissue cells by treatment with dilute trypsin was reintroduced by Scherer et al. (1953), Frisch and Jentoft (1953), Dulbecco and Vogt (1954) and Youngner (1954). The first group of workers employed it to remove from the glass and disperse aggregates of HeLa cells maintained in continuous cultures; the others applied it to the preparation of cell suspensions from tissue fragments. The suspensions are largely composed of single cells, although usually a varying number of small aggregates are included. When allowed to settle on a glass surface the cells rapidly adhere and in a suitable medium at 37° C increase in size and multiply. Eventually through their approximation, a monolayer is formed in which cytopathic changes induced by viruses or other agents can be visualized with great ease and clarity. It is possible with dispersed-cell suspensions to prepare rapidly and conveniently large numbers of uniform cultures. Formerly, methods for the enumeration of the cells introduced as well as the final cell population were unsatisfactory on the whole. The availability of dispersed-cell suspensions allows the experimental control of quantitative relations between cells and virus to a degree heretofore unattainable. Indeed, with cells from a trypsinized suspension it has even been possible to determine the rate and the quantity of virus produced by a single infected cell while observed under the microscope (Lwoff et al., 1955).

The development of the technic of preparing cell suspensions, together with the recognition of the cytopathic changes produced in vitro by viruses, has put in the hands of animal virologists the essential means for the quantitative study of cell-virus relationships which students of bacteriophages have long employed and has made possible many fundamental advances in knowledge.

Trypsinization of a variety of human and animal tissues—mature, embryonic and malignant—yields suspensions of fibroblastic and epithelial-like cells that readily form monolayers. Among these tissues, kidney and amniotic membrane have so far been employed most extensively. The procedure as described by Dulbecco and Vogt (1954) and Youngner (1954) has been modified subsequently in details by other workers with a view to increasing the cell yield and decreasing the number of manipulations. The modification proposed by Bodian (1956) fulfills these aims satisfactorily and will be given here as an example of the method.

The minced kidney cortical tissue from one monkey is placed in an Erlenmeyer flask with indentations at the base which serve to increase the efficiency of the process. Then 150 ml. of 0.25 per cent trypsin in Hanks' solution at pH 7.5 is added. With a magnetic stirrer the contents are mixed at a rate just short of bubbling at 4° C for 6 hours or at 22° to 26° C for 2 hours. The supernatant fluid that contains products toxic for cells is then removed and replaced with fresh trypsin solution. Stirring at 4° C is continued for 16 to 20 hours. The supernatant fluid containing the dispersed cells is removed from tissue residues and is slowly centrifuged (600 rpm) for 5 minutes. The packed cells are washed repeatedly in Hanks' solution and finally resuspended in sufficient growth medium to yield a suspension of about 300,000 cells per ml. This adjustment is made by counting the cells in a hemocytometer at the time of the last washing.

1. Simple Monolayer Cultures on Glass. At the present time the preparation of monolayer cultures consists simply in adding definite volumes of the cell suspension to

biochemical reactions of the cells are made difficult or impossible by the presence of the coagulum Finally, it may prevent uniform dissemination of virus throughout the cell population Therefore, the value of other substrates has been explored intensively Among those deserving particular mention are glass and agar Early work by Gey and Gey (1936) showed that cells could be propagated directly on glass In 1953, Morann and Melnick described a method for cultivating monkey kidney epithelial cells in this manner. By preheating the culture tubes at 45° C they found that the tissue fragments in the absence of excess fluid become adherent to the glass After a short interval at 40° C. the medium can be added without displacing the fragments. Then the cultures are left undisturbed for 10 to 14 days at 36° C, by which time sheets of epithelial cell outgrowth become established about many of the fragments This, like other fixed-fragment cultures, has been almost completely replaced by the dispersed cell culture

In 1937, Zinsser and his co-workers seeking a simplified technic for cultivating large quantities of typhus rickettsiae to be used in the manufacture of vaccine, distributed numerous fragments of chick-embryonic tissue on the surface of isotonic agar slants containing horse serum and Tyrode's solution Thus supported and nourished, the cells remained viable for several weeks Several species of rickettsiae as well as a number of viruses multiply actively under these conditions

Technics of Group I—Suspended Fragment Cultures. A system was described by the Maitlands in 1928 that offered to virologists greater simplicity and ease in preparation than most of those which have been described Therefore, it was adopted immediately and with various modifications was widely applied during the ensuing 20 years to the cultivation of viruses and rickettsiae. As with fixed-fragment cultures modern advances in technics have led to its virtual abandonment at present except in the production of large lots of virus for the manufacture of vaccine.

1. Original Method of Maitland and Maitland. A fine mince of fowl kidney tissue is prepared by chopping with scissors. Approximately 0 6 ml. of the mince is placed in an Erlenmeyer flask. Medium consisting of 12 ml. of Tyrode's solution and 6 ml of fowl serum is added, and the flask is tightly stoppered. Serial passages of the virus are carried out by introducing either a portion of the medium or a suspension of the ground fragments into freshly prepared cultures.

2. Modifications of the Maitland Technic. This basic procedure has been modified in various ways Modifications that warrant mention here are those introduced by Li and Rivers (1930), Simms and Sanders (1942), Plotz (1937) and Farrell and his co-workers (1953). Li and Rivers found that vaccinia virus multiplies in a medium consisting of tissue fragments suspended only in Tyrode's solution This represents the simplest form of tissue culture which has been devised so far Under these circumstances little or no cellular division occurs, as indicated by the virtual absence of mitosis on histologic examination of the fragments Nevertheless, in this medium chick-embryo cells survive for at least 4 weeks and retain the capacity to multiply when explanted in a complete medium (Enders and Pearson, 1941) Many viruses (Robbins and Enders, 1950), as well as the rickettsiae of typhus and Rocky Mountain fever, have been propagated in the system of Li and Rivers

By adding a few drops of chicken plasma to a mixture of serum, Tyrode's solution and chick-embryo tissue, Plotz (1938) found that the tissue fragments are gathered together in a network of fibrin which tends to float on the surface of the fluid Excellent yields of several viruses can be obtained by this method which permits considerable multiplication of the cells to take place.

Simms and Sanders (1942) introduced the use of an ultrafiltrate of serum instead of whole serum as a constituent of the medium in Maitland cultures Under these conditions they observed multiplication of several viruses The viruses of poliomyelitis and mumps were first cultivated in human non-nervous tissues suspended in a medium of this composition (Enders et al, 1949; Weller and Enders, 1949).

Farrell and his collaborators (1953) adapted the method to the large-scale propagation of poliovirus for the production of

The agar is melted in boiling water and cooled to 43° C The other constituents are brought to this temperature and mixed with the agar.

Hsiung and Melnick (1955) introduced a *simple but very useful modification of* Dulbecco's method. It consists merely of establishing the monolayer and the overlay on one side of a flat-walled bottle which subsequently is tightly stoppered In this way the necessity *of incubation in a humidified incubator in the* presence of CO_2 is eliminated Furthermore, the cells remain viable for a longer period, which permits the development of plaques produced by slowly growing cytopathogenic viruses (e g , Echo and certain Coxsackie viruses) that fail to appear in open Petri dishes (cf Fig. 48).

3 TECHNIC OF WALLACE AND HANKS FOR GROWING CELL COLONIES ON AGAR Wallace and Hanks (1958) have taken advantage of the availability of cell suspensions to produce colonies of cells in which the elements are more closely packed than in living tissues Small loops of a dense cell suspension are placed on agar slants or plates containing appropriate nutriments and incubated at 37° C Arrangements are made for renewal of the liquid phase by slow diffusion Under these conditions L strain mouse fibroblasts form large mucoid colonies during several months *of incubation The effect of viruses and* rickettsiae in cell colonies of this sort has not yet been studied, but it would seem that the technic might be applicable to analysis of host-virus relationships in a single type of cell under conditions more analogous in certain respects to those found in the living animal body than those offered in other types of cell culture

4 TECHNICS FOR THE CULTIVATION OF CELL CLONES A major obstacle to the precise analysis in vitro of viral multiplication as well as of other phenomena involved in virus-cell relationships has been the heterogeneous character of cell populations Primary cultures, whether derived from tissue fragments or [illegible] never can be regarded

geneous, since they originate from the heterogenous population of a primary explant Accordingly, one cannot assume that under these circumstances the behavior of individual cells exposed to virus will be uniform. A far greater uniformity of response not only to viral infection but in all other respects is to be anticipated in the case of a cell clone, i e , a *line derived from a single cell* Not long ago many investigators believed that clonal growth of mammalian cells could not be obtained because repeated experiments seemed to show that multiplication depended upon conditions established by the association of a certain minimal number of cells lying in close proximity Sanford and her collaborators (1948) *demonstrated the fallacy of this hypothesis* when they developed a clone of mouse fibroblasts This was achieved by drawing a single cell into a small capillary tube which was then immersed in a "conditioned medium," i e , medium in which a large population of cells had been grown previously For reasons

FIG 48 *Virus plaques in monolayer* cultures of monkey kidney cells with agar overlay prepared according to Hsiung and Melnick's *modification* (1955) of the technic of Dulbecco and Vogt. The plaques on the right were produced by poliovirus Type III, and those on the left by Echo virus type 8 Note difference in size and outlines of the plaques Approximately natural size (Hsiung, G D , and Melnick, J J Virology *1*, 533)

a vessel which may be of any desired shape or size and then allowing the cells to settle on the glass to which they rapidly become adherent When considerable numbers of replicate cultures in test tubes are required, aliquots of the stock suspension are conveniently dispensed into a series of test tubes by means of an automatic pipette while the cells are kept uniformly dispersed with a magnetic stirrer As routine the cultures are placed at 37° C, in a slightly slanted position and left undisturbed for several days In the pH color test for the assay of viral infectivity or titration of neutralizing antibodies (Salk et al, 1954) the tubes are maintained in a vertical position, allowing the cell layer to form on the bottom This test depends upon the fact that cells affected by the virus cease to metabolize. Accordingly, the pH of the medium remains high in comparison with that in cultures containing living cells which produce large amounts of acid metabolic end products (Robbins et al, 1950) In slanted tubes or in flasks monolayers usually develop after 5 to 10 days and consist of a sheet of contiguous cells as illustrated in Figure 45 At this time or subsequently the viral inoculum usually is introduced, although under certain circumstances, as in the pH color test, it may be added to the suspended cells when the culture is established After addition of the virus, the tubes or flasks are kept stationary, rotated or shaken mechanically. At present the simple monolayer culture is preferred to other types of tissue cultures for the routine propagation of all viruses that can be grown under these conditions.

2. Monolayer Cultures with Agar Overlay. The versatility of the monolayer culture was extended significantly by Dulbecco (1952) With the purpose of developing a technic that could be applied to mammalian viruses comparable with the plaque method of assay for bacteriophage, he covered the bottom of a Petri dish with chick-embryo cells dispersed by mechanical means. When the cells had spread out in the presence of a suitable medium, he exposed them to a dilute suspension of equine encephalomyelitis virus —an agent that was known to destroy rapidly the cells of this species. In order to confine the infection to the immediate neighborhood of the cells that were exposed to each of the few infective virus particles introduced in the inoculum, he covered the entire preparation with a thin overlay consisting of a mixture of agar, nutritive medium and neutral red Following incubation for several days at 37° C, discrete, circular translucent slightly yellowish areas were seen throughout the reddish sheet of cells These macroscopic effects or "plaques" were produced by the cytopathic effect of the progeny of the virus particles developing in the cells originally infected and then spreading, presumably by direct contact, to those adjacent Soon afterward, Dulbecco and Vogt (1954) improved the technic by substituting suspensions of trypsin-dispersed cells for the mechanically disrupted preparations initially employed

Because of the important role it now plays in mammalian virus research, the principal details of the method are presented. A heavy suspension of trypsinized monkey renal or other suitable cells is prepared in Earle's solution, and 2 ml is placed in each of a number of 60-mm pyrex dishes, then 1 5 ml horse serum and 0 75 ml chick embryo extract are added The cultures are incubated in a humidified incubator receiving a continuous flow of 3 per cent CO_2 in air The medium is changed every 3 days until a monolayer containing approximately 2×10^6 cells is formed. This usually requires 3 to 7 days with monkey renal cells Then the monolayer is washed twice with 2 ml of phosphate buffer saline solution After removal of the last washing fluid 0.3 ml of diluted virus suspension is pipetted onto the monolayer. The cultures are placed at 37° C. for 30 minutes to allow adsorption of virus to the cells which are then covered with 3 ml of melted agar overlay at a temperature of 43° C After solidification of the agar at room temperature the cultures are returned to the humidified incubator Under these conditions macroscopically visible plaques are produced by polioviruses types I and II within 24 hours.

The agar overlay consists of:

2.7% agar in distilled H_2O	12 parts
Neutral red in distilled H_2O	12 parts
Earle's salt solution 4x concentrated containing 400 μg of streptomycin and 400 units of penicillin per ml.	8 parts
50% chick embryo extract in Earle's solution	5 parts

Since the feeder-layer technic yielded nearly 100 per cent plating efficiency (as expressed by the ratio of number of single cells growing to number of cells plated), Puck and his associates reasoned that each cell possesses the potentiality for initiating unlimited growth, and that in consequence similar results without a feeder system might be obtained if proper conditions could be found Investigation led to the conclusion that cells were damaged considerably under the standard treatment with trypsin and washing in salt solution used to prepare the suspensions, and in consequence their growth capacity was impaired By taking precautions to minimize exposure to trypsin and salt solution and to reduce mechanical stress occasioned by repeated pipetting, a high plating efficiency was obtained when a few widely separated cells were allowed to settle directly on the bottom of Petri dishes and were supplied with an appropriate growth medium

The details of the method for obtaining clonal growth on glass have been summarized by these authors essentially as follows The medium is removed from a confluent sheet of HeLa cells grown in a bottle or Petri dish The cells are washed gently for a few seconds in a small quantity of balanced salt solution from which the calcium has been omitted The fluid is removed, and an equal volume of 0 05 per cent trypsin in salt solution of the same composition is added After 10 to 15 minutes at 37° C with occasional gentle agitation the action of the enzyme is arrested by addition at room temperature of an equal volume of complete growth medium The latter consists of Waymouth's mixture to which mammalian serum (human or horse, in varying proportions) and Hanks' solution are added The cell suspension is pipetted for the minimal time required to disperse aggregates, and the number of cells is determined in a hemocytometer Any desired aliquot of this suspension (of which 90 per cent or more of the cells are single) is added to a Petri dish (60 mm) containing 4 5 ml of growth medium The culture is incubated at 37° C in an atmosphere of 5 per cent CO_2 for 8 to 9 days Individual cell colonies that develop are removed and subcultured at the end of this time, or they may be stained with hematoxylin or Giemsa after fixation with Bouin's fluid When stained they have the general appearance shown in Figure 49

With the exception of the clonal line of L strain mouse fibroblasts (Sanford et al , 1948), as yet clonal stocks have been little studied in respect to their reactions with viruses or rickettsiae. There is no doubt, however, that in the future they will be regarded as essential in the analysis of certain problems in this area. Already Puck and Marcus (1956) have indicated one important application in experiments in which HeLa cells were exposed to large quantities of Newcastle disease virus The majority of cells were destroyed, but clonal strains were established with the survivors that later were shown to carry the virus for at least 2 years without exhibiting any morphologic abnormality This occult infection, analogous in certain respects to lysogeny in bacteriophage, was revealed by plating out cells from the infected line on feeder layers of x-irradiated HeLa cells The latter proved to be highly susceptible to the cytopathic effect of the virus harbored by the carrier line and were promptly destroyed

Technics of Group II—Suspended Cell Cultures. In the investigation of certain aspects of virus-cell relationships, it has become increasingly apparent that populations of submerged cells growing uniformly throughout a fluid medium would offer ideal materials for the more refined analysis of such fundamental problems as the mechanisms of virus adsorption, penetration and multiplication, the effect of virus on the growth of the cells, and the biochemical and morphologic changes induced in the cell by viral infection From the practical standpoint, systems of this sort would provide a continuous source of virtually unlimited quantities of cells for the routine preparation of monolayer cultures With these considerations in mind several workers during the last 5 years (cf Table 8) have shown that in cultures that are constantly agitated, a number of established cell lines can be propagated as submerged suspensions.

Of the various technics that have been described the most efficient appears to be the so-called spinner culture introduced lately by Cherry and Hull (1956) and by McLimans et al (1957a). To maintain the cells in suspension these authors employed a magnetic

that are not clear, subsequent attempts to obtain clones in this manner often failed.

Through the use of trypsinized cell suspensions Puck and his co-workers (1955a) have been able to overcome these difficulties by two procedures which are termed respectively the "feeder" layer and the glass-plating technic. The former consists in distributing a few dispersed cells over a confluent cell layer composed of the same elements which have been treated previously with x-rays to prevent their subsequent proliferation after the medium is added. The preparation is incubated for several days. During this time active multiplication of many of the unirradiated cells occurs, resulting in the formation of macroscopic colonies (cf. Fig. 49). Then the latter are subcultured in test tubes as clonal lines. In developing this method, Puck and his co-workers employed HeLa cells, which as components of the feeder layer were irradiated with 4,000 to 5,000 r. This dose does not kill these cells or grossly alter their metabolism. The feeder layer thus serves to "condition" the medium, enabling the few scattered unirradiated cells to divide.

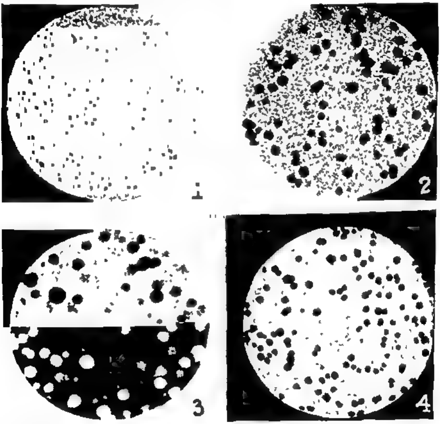

Fig. 49. Demonstration [illegible] for obtaining colonial growth [illegible] ura, 1955). Actual size. (1) [illegible] cells fixed with Bouin's solutic [illegible] (2) Comparable plate with layer of x-irradiated cells to which 100 unirradiated HeLa cells were added 8 days before photograph was taken; 97 colonies were counted. (3) Plate without feeder layer to which 100 HeLa cells [illegible]

countered in the standard aerobic system (Gifford and Syverton, 1957) Although analogous experiments will be necessary with other species of viruses before a final statement can be made, it would seem probable that multiplication will take place in any tension of *oxygen compatible with the viability of the* cells

Hydrogen-Ion Concentration. There is little evidence available to indicate that the fluctuations in hydrogen-ion concentration which ordinarily occur in cultures markedly

characterized by low pathogenicity for monkeys [illegible] delayed in slightly acid media as indicated by the slower formation of plaques in agar overlay cultures of monkey renal cells. The cytopathic changes induced by certain strains of Echo and Coxsackie viruses are also depressed or delayed when the pH of the medium is allowed to become acid (Barron and Karzon, 1957) This "pH effect," which

tions of Echo viruses from fecal specimens may be reduced significantly when acid-producing medium is used Such observations suggest that as routine the pH of the medium should be maintained as nearly as possible within physiologic limits during the cultivation of all mammalian viruses

Composition of the Medium. Numerous investigations have shown clearly that alterations in the composition of the medium may influence markedly the multiplication and the cytopathogenicity of animal viruses For example, Thicke and her co-workers (1952) found that the multiplication of poliovirus continued for a longer time in cultures maintained with medium 199 than in those nourished with Hanks' solution and ox-serum ultrafiltrate, and Scherer (1953) noted that the yield of herpes simplex virus was greater in cells nourished with serum and embryonic extract as compared with those maintained in a serum ultrafiltrate medium In cultures of monkey renal cells Melnick et al (1957) observed that the titer of poliovirus was moderately increased upon addition of cysteine to Hanks' solution Under the same circumstances glycine inhibited the rate of viral multiplication

The large body of data obtained in the past with a variety of agents in Li-Rivers' suspended fragment cultures suggested that their multiplication is not dependent upon the pres*ence of organic compounds, with the possible* exception of glucose. Lately, Melnick et al (1957), working with monkey renal cells, and Eagle and Habel (1956) with HeLa cells have demonstrated that this is true, at least in the case of poliovirus which [illegible] characterized by rapid multiplication in vitro In such instances [illegible] would seem that all organic factors required for viral synthesis except glucose are provided by integral constituents of the cell or its nutrient reserves

In considering the role of substances which appear to be requisite for viral multiplication, such as glucose, it should be borne in mind that this may be quite indirect, consisting perhaps merely in the preservation of cell viability during the period of viral synthesis Therefore, great caution must be exercised in drawing conclusions respecting the biochemical mechanisms involved in replication of virus based upon the effect of variations in the chemical composition of the medium.

That cytopathic changes caused by viruses can also be modified by the presence or the absence of certain nutrients is well illustrated by the observations of Reissig et al (1956) In cultures of human carcinoma cells (strain Hep 2) nourished with a medium consisting of serum, embryonic extract and amniotic fluid these authors noted that the virus of measles induces the formation of syncytia or large giant cells such as described by Enders and Peebles (1954) in cultures of human renal cells When glutamine was added a different sort of change took place, consisting in the assumption of an elongated, fibroblastic-like configuration by individual cells The concentration of glucose in the medium may influence the time at which cytopathic changes appear The presence of normal serum or tissue extracts tends to retard these manifestations of infection As yet only a beginning has been made in the definition of substances that

of this mode of action

stirring rod suspended by a wire attached to a swivel The rod was fixed at a suitable distance from the bottom of the vessel and rotated at a speed that prevented settling of cells but was insufficient to injure them by too violent collision As a further precaution against mechanically induced trauma, 0 2 per cent carboxymethyl cellulose, a substance of high viscosity, was incorporated in the medium which consisted of Eagle's mixture fortified with human, calf or horse serum In this system they demonstrated the continuous growth of L strain fibroblasts, HeLa cells, Chang's conjunctiva cells, human amnion cells and other established strains The capacity of the spinner culture vessels used by McLimans and his associates ranged from 25 to 500 ml From the largest of these 1×10^{6} to 3×10^{8} cells were harvested every 2 or 3 days Recently, McLimans and his collaborators (1957b) have shown that "L" cells can be propagated in commercially available fermentors of 5 liter unit capacity Agitation in the fermentor is accomplished by a mechanism analogous in principle to the spinner culture

FACTORS INFLUENCING INFECTION AND MULTIPLICATION OF VIRUSES IN CELL CULTURES

A number of factors have been defined that influence the multiplication and the cytopathogenicity of viruses in cell cultures, others still unrecognized no doubt exist and will be revealed by future research It has been emphasized already that the natural susceptibility or resistance of cells of different kind and origin is of primary importance In addition, it has been demonstrated repeatedly that variations in the physical, chemical and biologic conditions of the culture profoundly affect the behavior of the virus. Some of these conditions are: temperature of incubation, agitation of the system, oxygen supply, hydrogen-ion concentration and composition of the medium.

Temperature. Although cells in culture may survive for considerable periods when maintained at temperatures varying from about 4° to about 41° C., the range at which most viruses of human origin have been found to multiply is more restricted Little or no multiplication occurs below 20° to 25° C, and toward the upper limit of about 41° C. a slight increase in the temperature of incubation may completely arrest the growth. Thus, Enders and Pearson (1941) noted that influenza A virus (Melbourne strain) fails to multiply in chick-embryo tissue cultures maintained at 40° C., although the cells were not affected appreciably, and Gohd (1958) has shown that no multiplication of this virus (PR8 strain) occurs at 20° C. under similar conditions That the cytopathic effects of viruses may also be modified by changes in temperature is well demonstrated by the experiments of Bang et al (1957), who found that eastern equine encephalitis virus destroyed a strain of rat tumor cells almost completely at 37° C, but that little cytopathogenic effect was seen at 31° C In general, the range 35° to 37° C. employed as routine for the cultivation of mammalian viruses appears to be optimal

Agitation of the Culture System. The favorable influence of continued movement of the medium upon the growth of cells was recognized in the development of the roller-tube culture. That agitation of the system may also increase viral multiplication under certain circumstances is indicated by the observations of Farrell et al (1953), who obtained high yields of poliovirus in suspended fragment cultures of monkey renal cells when these were shaken continuously during the period of viral multiplication Frothingham (1957) has observed in stationary cultures of human amnion cells recently established that little or no proliferation occurs of a chick-embryo adapted strain of type II poliovirus (Roca-Garcia et al, 1952) In contrast a prompt increase accompanied by the appearance of cytopathic changes follows when comparable cultures are rotated With many agents, however, in other culture systems the effect of agitation is not so marked, as illustrated in the experiments of Melnick and Riordan (1952) with poliovirus

Oxygen Supply. Formerly, it was thought that an abundant oxygen supply was essential for optimal viral multiplication, but recently it has been demonstrated that poliovirus can multiply under almost completely anaerobic conditions in HeLa cell cultures and attain concentrations equivalent to those en-

cultures, Ann New York Acad Sc *58*, 1000-1011

APPLICATIONS

At present there scarcely remains any division of mammalian virology in which the tissue culture method has not found application. Its broad range of usefulness can be compared with that of the broth tube and the agar plate in the study of bacteria and bacteriophages. Indeed, it possesses some advantages not shared by bacterial media, since in certain situations it affords a satisfactory and even superior substitute for the experimental animal. Accordingly, the number of investigations that have depended upon the method as the essential tool is very large, and no attempt will be made to recapitulate here the results of even the most significant

In general, however, the broad applicability of tissue culture can be emphasized by merely listing the many areas of practice and research in which it is now being effectively employed These include

1 Isolation and identification of known viruses

2. Isolation and classification of previously unknown viruses

3 Quantitative determination of viral infectivity

4. Identification and quantitative determination of viral neutralizing, complement-fixing and antihemagglutinating antibodies in the diagnosis of apparent and inapparent infections

5 Development, production, safety-testing and standardization of antisera and vaccines

6. Epidemiologic and ecologic studies

7. Testing of chemical compounds for antiviral activity

8. Studies on the oncolytic properties of viruses

9. Analyses of the physical and chemical properties of viruses

10. Mechanism of viral infection of the cell

11 Mechanism of viral multiplication (kinetics)

12. Problems of natural resistance and susceptibility of cells to viruses

13. Cytopathology of viral infections

14. Variation, mutation and recombination in mammalian viruses

15. Viral interference

16. Mechanism of the reaction between virus and homologous antibody.

References to many advances made in these various areas by the tissue culture method will be found throughout this book. For others the reader is referred to the reviews by Ross and Syverton (1957), Parker (1950), Robbins and Enders (1950), and for the most recent, which have not yet been reviewed, to such publications as *Biological Abstracts.*

Serologic Reactions in Viral and Rickettsial Infections

INTRODUCTION

The several serologic procedures constitute an important basic methodology for the study of viral and rickettsial diseases and of their causal agents The importance of serologic methods is shown by the fact that the greatest proportion of examinations conducted in a diagnostic laboratory consists of serologic tests (Lennette, 1956); that epidemiologic investigations depend, to a major degree, upon serologic methods; and that such methods form an integral part of any approach to the study of the properties and the nature of viral and rickettsial agents, even in what are purely biochemical or biophysical investigations. Most of the methods represent adaptations of the basic bacteriologic or immunologic technics, the modifications having been necessitated through the inescapable use of crude, or weak, antigens or both In recent years, however, considerable progress has been made in freeing viral antigens of extraneous materials and in increasing their potency and sensitivity in in vitro tests.

Each of the several serologic tests is still performed in a greater or lesser variety of ways. As mentioned, some modifications were required by the relative impurity and insensitivity of the available antigens; some of the modifications, however, are referable to personal preference based on individual experience It is not possible here, nor desirable, to present in detail each of the various tests employed for each viral and rickettsial disease discussed in this book It is intended, rather, to present a general consideration of each of the basic immunologic procedures; the student interested in detailed descriptions of serologic procedures and methodologies is referred to the excellent compendium on technical procedures issued by the American Public Health Association's Committee on Diagnostic Procedures for Virus and Rickettsial Diseases (1956).

NEUTRALIZATION

The neutralization test is based upon the fact, dating from Sternberg's original observation with vaccine virus in 1892, that infection, overt or inapparent, with a viral agent leads to the development of a humoral antibody capable of neutralizing, or nullifying, the infective capacity of the agent. The test was used for many years before less complex but equally specific in vitro methods were developed and is still the standard against which the specificity of other methods is evaluated Neutralizing antibody, which is highly specific and generally accepted as the antibody responsible for the protective effect of im-

mune serum, is detected and assayed by inoculation of suitably prepared serum-virus mixtures into a host system that will serve as an indicator of the presence or the absence of active virus in the mixture, i e, whether neutralization of infectivity has or has not been achieved in the mixtures Since demonstration of infectivity requires the use of living tissues, the host systems employed are various animal species, but especially the albino Swiss mouse, the embryonated hen's egg, and mammalian or avian cell cultures

The neutralization technic is still employed comparatively widely Indeed, in some situations it may be the method of choice and, in others, the only serologic technic available. Thus, while the method may be used diagnostically to detect the appearance, or rise in titer, of neutralizing antibody during the course of a patient's illness or for the identification of a viral agent isolated from a patient, often the same objective can be reached by other, simpler procedures On the other hand, since neutralizing antibody may persist over many years, whereas the persistence of complement-fixing antibody, for example, is of relatively short duration, the neutralization test usually provides the only means to measure the extent to which a population has been immunized to a given virus Similarly, since artificial active immunization may lead to the development of little or no complement-fixing antibody, reliance must be placed upon the neutralization test, when other, simpler methods are lacking, to determine the immunogenic potency of the vaccine As is evident from the chapters dealing with specific diseases, the neutralization test, while highly valuable in virology, has found little application to the problems of the rickettsiologist

Technics for performing neutralization tests vary widely The emergence of certain modifications which stem from differences in host indicator systems might be expected Similarly, differences between agents may require the use of animal hosts of different ages or necessitate inoculation of the serum-virus mixtures by different routes Other differences in methodology, such as differences in the ratio of virus-to-serum volumes employed, incubation or nonincubation of serum-virus mixtures, differences in the time and the temperature of incubation, when this is employed, etc, indicate that a single method has not been found satisfactory for use with all viral agents, nor for the specific purposes to which the test is to be applied Despite the diversity of technics, the basic principle on which all the procedures are based is the same

Before outlining the framework on which neutralization tests are built, a few words are pertinent with respect to the measuring tools used to ascertain the infectivity of viral preparations and to determine the neutralizing capacity of immune serum Quantitation in virology involves the testing of a series of dilutions (of virus, of immune serum, etc) and the endpoint is generally represented by that dilution at which a certain proportion of the test animals reacts or dies A 100 per cent endpoint titer is unacceptable because its accuracy is affected so greatly by minor chance variations The most desirable type of endpoint is one based on an assay in which one half of the animals react, and the other one half do not Such an endpoint can be determined experimentally, but to do so requires the use of large numbers of test animals at closely spaced dilutions near the value for 50 per cent reaction Aside from other objections, the cost of the large number of animals used on every dilution in itself virtually precludes such a method for quantitation To circumvent such difficulties, Karber (1931) and Reed and Muench (1938) devised simpler methods for the estimation of 50 per cent endpoints The methods are described, and their use illustrated, in an article (Lennette, 1956) to which the interested student is referred As mentioned earlier, a series of dilutions of the test material to be assayed is made and inoculated into groups of animals, e g, 6 to 8 mice per dilution In such an assay, a large number of animals is used, and the 50 *per cent endpoint titer estimations are based* on the large *total* number of animals involved Computations based on the total number of animals used in the titration gives the effect "of using, at the two critical dilutions between which the endpoint lies, larger groups of animals than were actually included at these dilutions By inclining to equalize chance variations, the method tends to define the point more nearly than would be possible if it were simply interpolated between the two bracketing results" (Reed and Muench,

1938) The 50 per cent endpoint can be based on several types of reactions The most widely used endpoint in animal host systems is based on *mortality* and a written LD_{50} (50% lethal dose). The dose which *infects* 50 per cent of the test animals is written ID_{50}, the dose which *paralyzes* 50 per cent of the animals is represented by PD_{50}, etc With tissue culture systems, the term TCD_{50} or $TCID_{50}$ represents that dose of virus which gives rise to cytopathogenic changes or to colorimetric changes in 50 per cent of the inoculated cultures

The virus used in neutralization tests consists of a stock suspension whose infectivity or lethality endpoint is accurately known from replicate titrations previously done; knowledge of the endpoint permits preparation of the appropriate dilution or range of dilutions of the stock suspension to provide the requisite amounts of virus to be used in the examination of the serum The neutralizing capacity of a serum can be ascertained in either of two ways, namely, by the varying virus-constant serum method or by the constant virus-varying serum method The varying virus-constant serum method [illegible] used [illegible] als as [illegible] od, a series of virus dilutions is selected so that the control titration will cover the range of 100 per cent mortality at one end and 100 per cent survival at the other. The extent to which the infectivity of the virus is reduced by the test serum is a measure of the neutralizing capacity of the latter. Thus, in testing paired or multiple serum specimens obtained from a patient during the acute and the recovery or convalescent stages of an illness, the amount by which the recovery or convalescent phase serum specimen reduces the infectivity of the virus is compared with the amount of reduction in infectivity effected by the acute phase serum, which serves as the base line. Thus, the titer of the virus mixed with the acute phase serum may be 1×10^{-8}, whereas the titer of the virus mixed with the convalescent phase serum may be $1 \times 10^{-5.5}$; the difference between these two endpoint titers is $10^{2.5}$ or, arithmetically, approximately 300. This difference between the endpoint titers of the virus in the presence of the two sera is referred to as a "neutralization index" In this instance, the neutralization index is 300 Expressed in other terms, the neutralization index indicates the number of 50 per cent endpoint doses of virus, for example LD_{50}, that is neutralized by the convalescent phase serum as compared with the acute phase serum. In general, a neutralization index of 1 to 9 is regarded as negative, of 10 to 49 as equivocal, and of 50 or more as positive. Consequently, a diagnostically significant rise in neutralizing antibody titer is one in which the neutralization index, based on the comparison of acute and convalescent phase serums, is 50 or greater (log 1.7). In epidemiologic surveys, where only a single serum specimen from an individual is tested, the same criterion applies, i e, a positive serum is one capable of neutralizing 50 or more LD_{50} of virus.

With some viruses, the embryonated hen's egg can be used as a test species for neutralization tests. Most *in ovo* technics utilize the varying virus-constant serum method and, as in the case of animal tests, several types of endpoints may be used to express the neutralizing capacity of a serum. The first type of endpoint can be used with those viruses which produce plaques, or pocklike lesions, on the chorio-allantoic membrane Serum-virus mixtures representing a series of virus concentrations added to undiluted test serum are inoculated into embryonated hens' eggs. The degree of neutralization effected by the serum is reflected by the quantitative reduction in the number of virus particles capable of producing lesions, as indicated by the number of plaques produced. The procedure is time-consuming and open to a number of errors; reading and interpretation of the findings requires considerable experience. Replicate titrations of the infectivity of the virus alone are apt to vary markedly; when serum-virus mixtures are titrated, a further error arises from the lack of proportionality between virus dilutions and plaque counts (Jawetz and Coleman, 1952). A more nearly accurate endpoint for the quantitative measurement of antibody is that based on the lethal action of free virus in the mixtures; even so, the method has not found very wide acceptance in diagnostic virology, perhaps because most of the diseases with causal viruses which produce lethal effects in the chick embryo can be diagnosed by the much simpler in vitro serologic methods The third endpoint is feasible only with certain viruses, since it depends upon the appearance or the nonappearance in individual eggs of hemagglutinins or complement-fixing antigens, depending upon whether or not free virus is present in the serum-virus mixture. Determination of

such an endpoint is obviously much more cumbersome than is the determination of one based upon mortality.

With certain other viruses, quantitation of neutralizing antibody can be done in tissue culture systems A variety of tissues, both animal and human, and including human cancerous tissue, has been used In general, the sera are tested by the constant virus-varying serum method Basically, there are 3 different methods for conducting neutralization tests in tissue culture systems, viz, in monolayer cell cultures in tubes, in suspensions of dispersed cells, or by the plaque technic of Dulbecco and Vogt (1954a, 1954b) In the monolayer cell method (e g, monkey kidney epithelial cells, or strain HeLa human carcinoma cells), serial dilutions of serum, usually in 2-fold decrements, are tested against a standard dose of virus, usually 100 TCD_{50} as determined from prior titrations of the stock virus Each serum-virus mixture is inoculated into a group of several culture tubes The cultures are held in an incubator for several days and at intervals are examined microscopically Mixtures in which the virus is completely neutralized have no effect on cell growth, and the cell sheets appear to be normal Mixtures which contain free or unneutralized virus give rise to cytopathogenic changes in the cultures A 50 per cent endpoint for the neutralizing capacity of the serum can be computed, using the presence or the absence of cytopathogenic changes in the culture tubes as the basis for estimation

The second type of test, and one especially applicable to large-scale use, is performed with suspensions of susceptible cells This technic, generally referred to as the colorimetric test, the pH color test, or the metabolic-inhibition test, was first described by Salk et al (1954) for use with monkey kidney epithelial cells, a similar technic for use with HeLa cells was described by Lipton and Steigman (1955) and Robertson et al (1955) In this test, dilutions of serum are tested against standard doses of viruses, usually 100 TCD_{50} The serum-virus mixtures may be tested either in small tubes or in disposable plastic panels with indentations or cups to hold the mixtures To each serum-virus mixture is added a standard aliquot of cell suspension appropriately diluted to contain the desired number of cells in the aliquot used This test eliminates the need for cells which have grown out in a monolayer on glass The test is based on the fact that changes in the color of the phenol red indicator, i e, changes in pH level, reflect the metabolic activity of the cells Phenol red has a deep red color at pH 7 4 and above, but becomes salmon-colored, and finally yellow, as the pH drops to 7 2 and below Unneutralized virus present in a serum-virus mixture infects and kills the cells, since cellular metabolism is halted, the medium remains red Conversely, cells in the presence of a completely neutral serum-virus mixture are able to continue their metabolic activity with a resultant accumulation of acidic materials and a lowering of pH

The plaque technic of Dulbecco and Vogt (1954a, 1954b) can be used for the quantitation of neutralizing antibody (Dulbecco et al, 1956) This technic is based on the fact that certain viruses when mixed with a suspension of dispersed susceptible cells and then plated out give rise to plaques, or colonies, in a fashion analogous to the plaques obtained with bacteriophage The neutralizing capacity of the serum is indicated by the degree to which it can reduce plaque formation by the virus The technic permits highly accurate titrations of virus as well as very accurate determinations of antibody levels The method is most useful in basic immunologic and virologic studies, for ordinary diagnostic work and epidemiologic studies, it does not have the simplicity of the colorimetric method.

Neutralization of infectivity is not a property unique to specific antibody, since normal human and animal sera have been found to possess, in varying degree, the ability to effect nonspecific neutralization of certain viruses, e g, influenza, mumps, and Newcastle disease (Ginsberg and Horsfall, 1949) This nonspecific virus inactivating substance is heat-labile and storage-labile, it can be destroyed by heating at 56° C for 30 minutes or by simple storage of the sera at the usual icebox temperatures of 4° to 6° C. The role of this nonspecific inactivator in the neutralization reaction, and whether it should be preserved or eliminated from sera which are to be examined, is a debatable point Since this nonspecific factor can neutralize not inconsiderable amounts of virus, the use of unheated sera in neutralization tests would appear to be a hazardous procedure (Gins-

or by storage at icebox temperatures seriously diminishes the specific neutralizing capacity of an antibody-containing serum

1938). The 50 per cent endpoint can be based on several types of reactions The most widely used endpoint in animal host systems is based on *mortality* and is written LD_{50} (50% lethal dose). The dose which *infects* 50 per cent of the test animals is written ID_{50}, the dose which *paralyzes* 50 per cent of the animals is represented by PD_{50}, etc. With tissue culture systems, the term TCD_{50} or $TCID_{50}$ represents that dose of virus which gives rise to cytopathogenic changes or to colorimetric changes in 50 per cent of the inoculated cultures

The virus used in neutralization tests consists of a stock suspension whose infectivity or lethality endpoint is accurately known from replicate titrations previously done, knowledge of the endpoint permits preparation of the appropriate dilution or range of dilutions *of the stock suspension to provide the requisite* amounts of virus to be used in the examination of the serum. The neutralizing capacity of a serum can be ascertained in either of two ways, namely, by the varying virus-constant serum method or by the constant virus-varying serum method The varying virus-constant serum method is the one most commonly used in neutralization tests employing animals as the test indicator system In this method, a series of virus dilutions is selected so that the control titration will cover the range of 100 per cent mortality at one end and 100 per cent survival at the other The extent to which the infectivity of the virus is reduced by the test serum is a measure of the neutralizing capacity of the latter Thus, in testing paired or multiple serum specimens obtained from a patient during the acute and the recovery or convalescent stages of an illness, the amount by which the recovery or convalescent phase serum specimen reduces the infectivity of the virus as compared with the amount of reduction in infectivity effected by the acute phase serum, which serves as the base line. Thus, the titer of the virus mixed with the acute phase serum may be 1×10^{-8}, *whereas the titer of the virus mixed* with the convalescent phase serum may be $1 \times 10^{-5.5}$, the difference between these two endpoint titers is $10^{2.5}$ or, arithmetically, approximately 300. This difference between the endpoint titers of the virus in the presence of the two sera is referred to as a "neutralization index" In this instance, the neutralization index is 300 Expressed in other terms, the neutralization index indicates the number of 50 per cent endpoint doses of virus, for example LD_{50}, that is neutralized by the convalescent phase serum as compared with the acute phase serum In general, a neutralization index of 1 to 9 is regarded as negative, *of 10 to 49 as equivocal, and of 50 or more* as positive. Consequently, a diagnostically significant rise in neutralizing antibody titer is one in which the neutralization index, based on the comparison of acute and convalescent phase serums, is 50 or greater (log 1.7) In epidemiologic surveys, where only a single serum specimen from an individual is tested, the same criterion applies, i e, a positive serum is one capable of neutralizing 50 or more LD_{50} of virus.

With some viruses, the embryonated hen's egg can be used as a test species for neutralization tests Most *in ovo* technics utilize the varying virus-constant serum method and, as in the case of animal tests, several types of endpoints may be used to express the neutralizing capacity of a serum. The first type of endpoint can be used with those viruses which produce plaques, or pocklike lesions, on the chorio-allantoic membrane Serum-virus mixtures representing a series of virus concentrations added to undiluted test [illegible] ...ated hens'

duction in the number of virus particles capable of producing lesions, as indicated by the number of plaques produced The procedure is time-consuming and open to a number of errors, reading and interpretation of the findings requires considerable experience Replicate titrations of the infectivity of the virus alone are apt to vary markedly; when serum-virus mixtures are titrated, a further error arises from the lack of proportionality between virus dilutions and plaque counts (Jawetz and Coleman, 1952). A more nearly accurate endpoint for the quantitative measurement of antibody is that based on the lethal action of free virus in the mixtures; even so, the method has not found very wide acceptance in diagnostic virology, perhaps because most of the diseases with causal viruses which produce lethal effects in the chick embryo can be diagnosed by the much simpler in vitro serologic methods The third endpoint is feasible only with certain viruses, since it depends upon the appearance or the nonappearance in individual eggs of hemagglutinins or complement-fixing antigens, depending upon whether or not free virus is present in the serum-virus mixture. Determination of

generally, but not invariably, possess activity. How enhancement of the viral content of a tissue, with a concomitant increase or appearance of complement-fixing antigen, can be effected by substitution of a more susceptible cell for a less susceptible one, is exemplified by dengue virus. When this virus is propagated in the infant mouse brain, it attains much higher infectivity levels than it does in the adult mouse brain, this marked increase in concentration is accompanied by the appearance of practical amounts of complement-fixing antigen in the tissue. Similarly, the yield of complement-fixing antigen can be increased by increasing the number of susceptible cells available for viral synthesis, as has been done for poliomyelitis viruses in tissue culture (Schmidt et al., 1957). Lastly, the development of suitable antigens has also been based upon the ability to achieve some purification of crude tissue suspensions through the removal of undesirable extraneous materials.

Crude tissue suspensions, although they may be rich in viral content and in the products of viral growth, are generally unsatisfactory as antigens from one or more standpoints; this is especially true of CNS tissue suspensions containing any one of a number of neurotropic viruses. The crude brain tissue suspensions tend to be anticomplementary in variable degree, but even when free of such reactivity they frequently show a tendency to fix complement in the presence of normal sera. This phenomenon has been attributed, in part, to the presence in normal serum of a natural antibody which reacts with some constituent of normal tissue (Kidd and Friedewald, 1942); this natural antibody can be destroyed by heating at temperatures (60° to 65° C.) higher than that generally used for inactivation (56° C.), and the reacting substance in the antigen can be removed by high-speed centrifugation. Maltaner's work (1946) suggested that the reaction is entirely nonspecific in nature and due to a cephalinlike substance present in tissue extracts; he showed that many tissue suspensions used as antigens possess thromboplastic activity, that inactivated human serum enhances the thromboplastic activity of such antigens, and that there is a direct correlation between thromboplastic activity and the occurrence of nonspecific fixation. In addition to this tendency to react with normal sera, crude antigens also have a propensity to give fixation with Wassermann positive sera. Lastly, crude tissue antigens, if not anticomplementary initially, tend to become so with storage.

The removal of substances responsible for nonspecific and anticomplementary reactivities is based essentially on 3 different approaches, viz., (1) high-speed centrifugation, (2) repeated freezing and thawing and (3) extraction with lipid solvents. The conclusion of Kidd and Friedewald (1942) that a sedimentable constituent of normal tissue is involved in nonspecific reactions was substantiated by Havens et al. (1943); the latter workers found that antigens free of the sedimentable fraction could be used with sera heated at 56° C. and that higher inactivating temperatures were not required. Experience in the author's laboratory with chick-embryo-derived antigens indicates that nonspecifically reactive substance can be largely, but not entirely, sedimented by high-speed centrifugation; the purified antigens occasionally react with normal serum, although the incidence of such nonspecific reactions is markedly less as compared with crude antigen preparations (Lennette et al., 1956).

Casals and Palacios (1941) noted that high-speed centrifugation, especially if followed by Seitz filtration, served to remove much of the nonspecific and anticomplementary activity of infected mouse-brain suspensions. Because filtration was accompanied by reduction in antigenicity, they preferred to subject their crude tissue emulsions to repeated freezing and thawing which served to flocculate nonspecifically reactive materials; however, the use of antigens purified by this procedure required inactivation of the test sera at 60° to 65° C., depending upon the animal species of origin of the serum.

At the present time, antigens for the neurotropic virus diseases are prepared from infected mouse-brain suspensions extracted with lipid solvents to remove nonspecifically reactive substances. Although earlier workers had used lipid solvents for the purification of precipitating antigens (Craigie and Tulloch, 1931) and complement-fixing antigens (Howitt, 1937), the method was not utilized widely until its reintroduction by DeBoer and Cox (1947). The method of the latter workers was simplified and considerably shortened, in

Karzon's studies (1956) on the nature of the nonspecific virus inactivator present in human and mammalian sera suggest that the nonspecific neutralizing factor active against Newcastle disease virus is related to properdin. The investigations of Wedgwood et al (1956) indicate that the properdin system is probably identical with the inhibitors which have been described for the mumps, influenza A and B, and Newcastle disease viruses, and that it can inactivate these viruses in the absence of antibody The fact that specific neutralizing capacity which has been lost by storage or heating of the serum can be restored entirely, or in major part, by the addition of fresh normal serum, points to the existence of a potentiating factor in human and mammalian sera This potentiating factor may also be identical with the properdin system, since the participation of specific antibody in the neutralization reaction does not preclude the participation of the properdin system—both may act synergistically (Wedgwood et al, 1956)

What processes might be involved in the neutralization of viruses by specific immune sera has always posed a question of considerable interest and one not entirely answered as yet. The observation of Andrewes (1928) that noninfectious mixtures of vaccine virus and immune serum, or virus III and immune serum, became infective on dilution, i e, were reactivated, was confirmed subsequently by a number of investigators working with a variety of viruses These findings led to the opinion that no in vitro union of virus and neutralizing antibody occurs, and that the reactivation phenomenon is peculiar to viruses Craigie (1939) evaluated the available evidence and concluded that both ideas were erroneous, i e., union of virus and antibody does occur in vitro and reactivation of neutral mixtures does not occur. The most recent studies on the kinetics of the neutralization test are those of Dulbecco et al (1956), who used the western equine encephalomyelitis and type 1 poliomyelitis viruses as models, and the plaque method of assay which, as mentioned above, is a highly accurate method for the quantitation of virus and of antibody It was found that neutralization proceeded with time as a first order reaction; its rate was proportional to the concentration of antibody present and was affected by temperature No reactivation (poliomyelitis virus) or only a slight reactivation (western equine encephalomyelitis virus) occurred when serum-virus mixtures were diluted. This lack of reactivation is contrary to experiences previously reported, as mentioned above It seems likely that the reactivation reported by many previous investigators may have been a spurious phenomenon resulting from inadequacies of the assay method which permitted free antibody and virus to be carried over into the quantitating system (susceptible host) with consequent further possible interaction between the two. However, some reactivation of the western equine encephalomyelitis virus could be effected if a high titered virus preparation were added to the virus-serum mixture; either active or ultraviolet light inactivated virus could be used to bring about reactivation Such reactivation is thought to arise from the collision of free viral particles with the virus-antibody complexes

COMPLEMENT FIXATION

The simplicity of the complement-fixation test and the rapidity with which results can be obtained led many earlier workers to attempt application of the method to virologic problems These attempts were, on the whole, either negative or equivocal (Sosa-Martinez and Lennette, 1955) Much of the early difficulty was referable to the crudeness of the antigens available at that time. Over the past 10 to 15 years, however, as antigens of adequate potency and sensitivity have been developed, the method has become an increasingly important one in both theoretical and applied virology. Although the test may be performed with a number of variations in procedural detail (Lennette, 1956), the immunologic principles on which it is based are identical, whether viral, rickettsial, bacterial or other types of antigens are employed.

The development of suitable antigens has rested on several considerations. Generally speaking, the complement-fixing activity of an infected tissue is roughly related to its viral content as measured by infectivity, i e., tissues with a viral content below a certain infectivity level may possess no demonstrable complement-fixing capacity, whereas tissues with a viral content above that critical level

sist, are difficult to make. Thus, in mumps and influenza, complement-fixing antibody appears early, i e , during the first week or 10 days after onset, whereas in poliomyelitis, complement-fixing antibody appears late, i e , frequently during the third or fourth week after onset of symptoms. In the first two diseases, frequently a diagnosis can be made on the mere presence in the acute-phase serum of appreciable amounts of antibody to the S (soluble) complement-fixing antigen, whereas in poliomyelitis, the existence of S (soluble) and V (viral) antigens remains to be ascertained definitely. In most neurotropic viral diseases, complement-fixing antibodies appear later than do neutralizing antibodies; an exception is lymphocytic choriomeningitis, in which the reverse occurs As to the maximal titers attained, levels of 1 128 and higher are not exceptional in the rickettsial and the pneumotropic viral diseases and in some neurotropic

somewhat longer in the rickettsial diseases In some instances, immunization leads to the appearance of complement-fixing antibody, in others it does not Information on which situation obtains, in any given instance, is basic to laboratory diagnosis, which may have to rest upon the ability of the virologist to distinguish between antibody engendered by immunization and that elicited by infection

The complement-fixation test can sometimes be applied to the rapid identification of newly isolated viruses Smadel and Wall (1941) used the test for the rapid identification of lymphocytic choriomeningitis virus in animals inoculated with clinical material from patients, Hummeler et al (1952) used it for the identification of newly isolated influenza viruses, and Lennette et al (1956b) used it for the identification of western equine encephalomyelitis virus in embryonated hens' eggs inoculated with suspensions of infected mosquitoes In addition to its usefulness in the identification of viruses, the test has been applied recently to the typing of viruses which exist in a number of immunologic groups, for example the adenovirus group (Pereira, 1956) and poliomyelitis viruses (LeBouvier et al , 1954, Schmidt and Lennette, 1957)

The sera of certain avian and mammalian species exert an inhibitory effect in specific complement-fixation systems (Rice, 1948), and consequently an indirect method for detecting the occurrence of fixation has to be employed The indirect complement-fixation technic is widely employed for the detection of Newcastle disease antibodies (Wolfe et al , 1949) in the sera of fowl, and for the detection of specific antibody in the sera of chickens, ducks, turkeys, pheasants and other avian species infected with ornithosis virus (Karrer et al , 1950; Hilleman et al , 1951) The inhibitory antibody lacks the ability to combine with guinea pig complement, although it has the capacity to combine with

infected pigeons or humans, or from immunized animals, such as the rabbit If, in an avian serum-ornithosis antigen mixture, the inhibiting antibody unites with the antigen, no antigen is available to combine with the specific indicator antibody and the guinea pig complement, hence, hemolysis of the red cells in the hemolytic system occurs If the avian serum lacks antibodies, the indicator antibody fixes the complement in the presence of specific antigen, no free complement is available, and hence no hemolysis occurs when the hemolytic system is added

The conglutinating complement absorption test (CCAT) represents another modification of the complement-fixation technic and has

lysis The test system consists of dilutions of the serum under examination, antigen and nonhemolytic complement (cat or horse serum) After appropriate incubation of the mixture, the conglutinating system is added,

hemagglutinin present in fresh bovine serum which reacts with a sensitized cell in the presence of nonhemolytic complement. If the test serum contains antibody, complement is

terms of the time required for the processing procedure, by España and Hammon (1948), but it is potentially hazardous since it involves extraction of a highly infectious powder *obtained by lyophilization of the virus suspension* More recently, Casals (1949) has described the preparation of acetone-ether extracted antigens The *advantages of this* method lie in the fact that highly specific antigens can be produced in less than one day, and no special equipment is necessary For details of this method the reader is referred to *the original publication (Casals, 1949)*

Many of the neurotropic viruses possess some degree of viscerotropism, but the affinity for visceral tissue usually is of so relatively low an order that both the virus content and the complement-fixing antigen content of the affected organs is low. One outstanding exception is lymphocytic choriomeningitis virus, the spleens of guinea pigs infected with this virus are a comparatively rich source of specific antigen (Smadel et al, 1939) Similarly, while many neurotropic viruses can be propagated in the embryonated hen's egg, the growth of only a few of them is accompanied by the appearance of satisfactory amounts of complement-fixing antigen in the membranes or the fluids, mention might be made of Murray Valley encephalitis virus (French, 1952), lymphocytic choriomeningitis virus (Whitney et al., 1953), herpes simplex virus (Sosa-Martinez and Lennette, 1955), and western equine encephalomyelitis virus (Lennette et al., 1956). It seems likely that infected tissue culture fluids will serve as the starting material for the preparation of complement-fixing antigens for an increasing number of viral agents. Fluids as antigens are already used in several instances, e.g, the adenovirus group (Hilleman and Werner 1954. Huebner et al, 1954) and, among the neurotropic agents, poliomyelitis viruses (Schmidt and Lennette, 1955) At the present time, however, infected brain tissue is still the chief starting material for the preparation of complement-fixing antigens for neurotropic viruses

Highly satisfactory complement-fixing antigens for the diagnosis of the common rickettsial diseases *can be prepared from the appropriate* rickettsial agent by any of several technics, all of which are based on extraction of infected tissue suspensions with lipid solvents (Smadel *in* American Public Health Association Committee, 1956; Topping and Shepard, 1946). Depending upon the procedure employed, either type-specific or group-specific *antigens can be prepared. Type-specific antigens*, which usually permit differentiation of closely related rickettsial infections, are *indispensable in those situations where it is* highly important to determine with exactitude the rickettsial agent responsible for illness in a given patient, or for a given outbreak Group-specific antigens, on the other hand, *are adequate for most diagnostic purposes, as they serve to differentiate infections* caused by the epidemic typhus-murine typhus group from those caused by other rickettsiae The reader interested in methods for preparing rickettsial antigens is referred to the excellent description of Smadel (*American Public Health Association Committee, 1956*).

Detailed descriptions of the complement-fixation test as applied to the diagnosis of viral and rickettsial diseases are given elsewhere (see various chapters in American Public Health Association Committee, *1956*). Additional description of this comparatively well-known method is not warranted here, and the reader desiring details of methodology is referred to the sources just mentioned. The method employed in the author's laboratory, and standardized for use with a number of viral and rickettsial diagnostic antigens, is also described in those sources (see Jensen *in* American Public Health Association Committee, 1956).

Application of the complement-fixation test in the diagnosis of viral and rickettsial infections necessitates not only a thorough familiarity with the technic, its advantages, disadvantages and inherent pitfalls but also some familiarity with the clinical features of specific infections and, ideally, some knowledge of the epidemiologic characteristics of the various disease entities The same desiderata hold true for other tests in the diagnostic armamentarium but are emphasized here because *of the increasingly wider application that* is being made of the complement-fixation method

Generalizations as to the time of appearance of complement-fixing antibodies, the maximal titers that are attained, and the length of time over which such antibodies per-

after onset, whereas in poliomyelitis, complement-fixing antibody appears late, i e, frequently during the third or fourth week after onset of symptoms *In the first two diseases,* frequently a diagnosis can be made on the mere presence in the acute-phase serum of an-

Y (viral) antigens remains to be ascertained definitely. *In most neurotropic viral diseases,* complement-fixing antibodies appear later than do neutralizing antibodies; an exception is lymphocytic choriomeningitis, in which the reverse occurs As to the maximal titers attained, levels of 1:128 and higher are not exceptional in the rickettsial and the pneumotropic viral diseases and in some neurotropic viral diseases, although in the latter group, as

infection with a neurotropic virus but persist somewhat longer in the rickettsial diseases In some instances, immunization leads to the appearance of complement-fixing antibody, in *others it does* not *Information on which situation* obtains, in any given instance, is basic to laboratory diagnosis, which may have to rest upon the ability of the virologist to distinguish between antibody engendered by immunization and that elicited by infection

The *complement-fixation* test can sometimes be applied to the rapid identification of newly isolated viruses Smadel and Wall (1941) used the test for the rapid identification of lymphocytic choriomeningitis virus in animals inoculated with clinical material from patients, Hummeler et al (1952) used it for the identification of newly isolated influenza viruses, and Lennette et al (1956b) used it for the identification *of western equine* encephalomyelitis virus in embryonated hens' eggs inoculated with suspensions of infected mosquitoes *In addition to its usefulness in the identification* of viruses, the test has been applied recently to the typing of viruses which exist in a number of immunologic groups, for example the adenovirus group (Pereira, 1956) and poliomyelitis viruses (LeBouvier et al, 1954; Schmidt and Lennette, 1957)

The sera of certain avian and mammalian species exert an inhibitory effect in specific complement-fixation systems (Rice, 1948), and consequently an indirect method for detecting the occurrence of fixation has to be employed The indirect complement-fixation technic is *widely employed* for the detection of Newcastle disease antibodies (Wolfe et al, 1949) in the sera of fowl, and for the detection of specific antibody in the sera of chickens, ducks, turkeys, pheasants and other avian species infected with ornithosis virus (Karrer et al, 1950, Hilleman et al, 1951) *The inhibitory antibody lacks the ability to* combine with guinea pig complement, although it has the capacity to combine with

dicator antibody is obtained from naturally infected pigeons or humans, or from immunized animals, such as the rabbit If, in an avian serum-ornithosis antigen mixture, the inhibiting antibody unites with the antigen no antigen is available to combine with the

fixes the complement in the presence of specific antigen, no free complement is available, and hence no hemolysis occurs when the hemolytic system is added

The conglutinating complement absorption test (CCAT) represents another modification *of the complement-fixation technic* and has been employed in studies of Q fever, vaccinia, influenza and the psittacosis-lymphogranuloma venereum group of infections (Wolfe and Kornfeld, 1948, Stoker et al, 1950, and Hilleman et al, 1951). In this modification, the occurrence of specific antigen-antibody *union is revealed by agglutination* of erythrocytes in the indicator system and not by their lysis. The test system consists of dilutions of the serum *under examination, antigen* and nonhemolytic complement (cat or horse serum) After appropriate incubation of the mixture, the conglutinating system is added, *thus consists of sheep erythrocytes that have* been sensitized with the natural hemagglutinin present in bovine serum and of conglutinin a hemagglutinin *present* in fresh bovine serum which *reacts* with a sensitized cell in the presence of nonhemolytic complement If the test serum contains antibody, complement is

bound, and none is available to react in the conglutinating reaction, so that no agglutination of the erythrocytes occurs The CCAT is not as simple to perform as a direct or hemolytic complement-fixation test, and the advantage of increased sensitivity is offset by this factor, plus the generally higher incidence of anticomplementary and nonspecific reactions

AGGLUTINATION AND PRECIPITATION

In the earlier literature on virology, the in vitro aggregation of viral or rickettsial materials by specific antisera was generally referred to as "flocculation" This broad term, which embodies both agglutination and precipitation, is still used to describe those situations in which it is difficult to determine whether the reacting antigen is a suspension of particles or a solution

When aggregation is due to the clumping of relatively large particles such as elementary bodies or rickettsiae, particles readily seen by ordinary microscopy, the term *agglutination* is permissible and appropriate. The term *precipitation* is reserved for those reactions in which the aggregating material comes out of solution as, for example, the soluble LS antigen of vaccinia However, absolute differentiation of the type of reaction on the basis of the particle size of the reacting antigen is not always feasible—the soluble antigen of *R prowazeki*, for example, is particulate, its size being considerably smaller than that of the rickettsial body itself and approximating that of the smallest viruses

In general, the term "flocculation" should be applied to aggregation effected by specific immune serum in materials known to contain both large particles and soluble antigen, or manifested in materials in which the physical nature of the antigen is uncertain. This is well exemplified by vaccinia virus. Convalescent sera to vaccinia virus contain at least 4 different antibodies, namely, L, S, NP and X (Chap 32), all of which have the capacity to agglutinate the elementary bodies of vaccinia In addition, the L, S and NP antibodies [illegible]

ployed Consequently, aggregates appearing in a mixture of vaccinial antigen and specific antiserum may consist of viral particles agglutinated by any one or all of the antibodies mentioned above, as well as of LS antigen precipitated by either of its antibodies.

Flocculation reactions have been described for a number of viruses including, recently, the viruses of mumps, Newcastle disease, influenza (Belyavin, 1957) and poliomyelitis (Smith et al, 1956). In some cases the concentration of virus present in crude suspensions of infected tissue is adequate to produce visible floccules, but not infrequently such preparations contain inhibitory substances (Belyavin, 1957) The inhibitors may be removed by such simple procedures as adsorption and elution of the virus from erythrocytes (influenza viruses), adsorption and elution followed by further purification by high-speed centrifugation (Newcastle disease virus), or purification by high-speed centrifugation alone (mumps virus). Those viruses which show flocculation in the presence of specific antisera almost invariably possess the capacity to fix complement specifically This is true, for example, of the viruses just mentioned. However, the converse is not always true—a number of viruses which are reactive in the complement-fixation system do not give demonstrable flocculation However, this may be due to differences in the amount of serologically reactive material required to bring about these reactions In general, detectable fixation of complement requires appreciably smaller amounts of antigen than does visible flocculation Infected fluid from HeLa cell cultures of poliomyelitis virus, for example, may be *diluted* 6- to 8-fold or more for use in the complement-fixation test (Schmidt et al, 1957) whereas it must be *concentrated* 40-fold or more to provide a suitable antigen for the flocculation reaction (Smith et al, 1956). Similarly, about 10 times more of a washed suspension of *Rickettsia prowazeki* is required for demonstrable agglutination than is necessary to give specific fixation of complement.

Agglutination tests are feasible with the rickettsiae and with some of the larger mammalian viruses. Several technics, viz, the macroscopic, the microscopic and the capillary, are employed. The macroscopic, or tube, method requires comparatively large amounts

of antigen, and to circumvent this undesirable feature, microscopic and capillary technics have been devised Thus, the macroscopic method can be used for the routine diagnosis of Q fever (Lennette et al 1952), but to conserve materials Babudieri (1953) devised a microscopic technic in which very minute amounts of antigen and antiserum are used, the reagents are mixed in droplet amounts on glass slides, and the reaction is read microscopically. Recently, a capillary tube agglutination test has been described for the detection and the assay of antibody against *Coxiella burnetii* (Luoto, 1956) The antigen which consists of stained rickettsiae is drawn into a capillary tube which is then filled with the serum or other material to be tested for antibody content The ends of the tube are sealed with clay or wax and the tubes are incubated in a vertical position for several hours, the aggregates of agglutinated rickettsiae which form are readily visible macroscopically

As is mentioned below (see Indirect Hemagglutination), red blood cells can be coated with viral antigens, and since they then become agglutinable by specific immune serum such treated cells can be used for antibody assay and even for diagnosis Attempts have been made to utilize other insoluble particles, e g , bacteria (Roberts and Jones, 1941), collodion (Goodner, 1941) or insoluble dyes (Smorodintsev and Fradkina, 1944) as carriers of specific serologically reactive antigens so that in the presence of antibody large, readily visible aggregates would form None of these methods has proved to be entirely satisfactory for diagnostic purposes

More recently Segre (1957) has adapted this fundamental technic to the detection of viral antigens Antibodies against the viruses of hog cholera and of vesicular stomatitis were adsorbed onto finely divided particles of a basic anion exchange resin When such antibody coated resin particles were mixed with serum taken from swine during the viremic phases of infection with these viruses, specific agglutination of the coated particles occurred Serum antibodies to these two viruses can be detected by means of agglutination-inhibition test based on the use of antibody coated resin particles (Segre, 1957).

VIRAL AND RICKETTSIAL HEMAGGLUTINATION

In 1941 Hirst, and McClelland and Hare, independently reported that influenza virus possesses the capacity to agglutinate chicken erythrocytes Subsequently, a miscellany of other viruses has been found to possess hemagglutinative activity The heterogeneity of viruses comprising the group with hemagglutinative properties is indicated by the fact that they range in size from the smallest (e.g , foot and mouth disease virus) to the largest viruses (e g , vaccine virus), possess varying tissue tropisms and vary in the spectrum of red cells which they will agglutinate

Because of differences in the nature of the hemagglutinins produced by different groups of viruses, differences in their behavior, and in the physical and chemical conditions under which they can be demonstrated, etc., it is not possible to treat these agents as a single group characterized by hemagglutinative properties Certain generalizations may be made but it is necessary to discuss the hemagglutinative viruses in terms of groups which exhibit certain features in common

Broadly speaking, agglutination of red cells by viral agents is classifiable into two types of reactions, viz direct hemagglutination and indirect hemagglutination Direct hemagglutination, the type originally described by Hirst and by McClelland and Hare, and sometimes referred to as the Hirst phenomenon, results from the action of the viral particle itself, or of some substance intimately associated with viral synthesis or with the action of the virus on the infected cell, directly upon the erythrocyte Indirect hemagglutination results from exposure of red cells coated with a viral or rickettsial antigen to the action of specific immune serum, the interaction of viral antigen with specific immune serum results in clumping and sedimentation of the sensitized cells

In the case of those viral agents which produce direct hemagglutination, this property can be utilized for assay of the viral content of a preparation and also for quantitation of specific antibody the so-called [illegible]

all those viruses which produce direct hemagglutination, the facility with which quantitation of hemagglutinative capacity or of specific inhibiting antibody can be accomplished varies considerably, ranging from the quite simple test to the relatively complicated procedure

Methods based on red cell agglutination and on specific inhibition of agglutination are, with the exception of the technics dealing with arbor viruses (Chap 12), described in considerable detail elsewhere (American Public Health Association Committee, 1956), the reader is referred to that source For details of the methodology involved in hemagglutination and hemagglutination-inhibition tests with arbor viruses, reference should be made to the original publications (see below).

Direct Hemagglutination

The group of viruses characterized by direct hemagglutinative action may be divided into several subgroups:

The first subdivision includes the viruses of influenza, mumps and Newcastle disease, i e , myxoviruses Because hemagglutination by these viruses occurs under very simple conditions and so is quite readily demonstrable, this

ing description is based Hemagglutination is associated with attachment of the viral particles themselves to the red cell This is not a matter of simple adsorption, since spontaneous elution of virus also occurs and, under proper condition, may even be complete The eluted virus does not appear to be altered in any way, although the red cells are no longer able to adsorb fresh virus of the same type The surface of the red cell contains receptors which are mucoprotein in nature and provide a point for virus attachment. On the surface of the virus elementary body, in turn, are certain chemical groupings or effectors with a pattern complementing that of the receptors on the cell Union between elementary body and red cell is thus a linkage of effector with specific receptor. The virus possesses an enzyme, now identified as a glycosidase (Gottschalk, 1956), with the ability to destroy receptors. Destruction of the receptors leads to release of virus from the surface of the red cell.

The second subdivision is comprised of viruses (variola, vaccinia, ectromelia, meningopneumonitis) whose marked hemagglutinating activity is also readily demonstrable but which, unlike that of the first group, is due to a soluble fraction completely separable from the viral particle The hemagglutinin can be separated from the virus by high-speed centrifugation or by filtration through virus-retaining filters The fact that only the largest viruses have been found, thus far, to have hemagglutinins separable from the viral particle may be significant. As in the case of the first group, the hemagglutinative activity can be inhibited by specific antibody.

The third subdivision consists of the arthropod-borne (arbor) viruses. Uncertainty exists as to whether hemagglutination by these agents is a function of the viral particle itself or of some other factor closely associated with it. Methods for the demonstration of hemagglutinins and specific inhibitory antibodies are based on the findings of a number of workers (Warren et al , 1949; Chanock and Sabin, 1953, Casals and Brown, 1954; Porterfield, 1954; Clarke and Casals, 1955, Clarke and Theiler, 1955) and Rockefeller Foundation Virus Laboratory Technical Manual on Hemagglutination (unpublished, 1955). These methods have been gradually improved, simplified and extended to additional viruses in this group and are now being used as standard procedures in specialized laboratories Although with some arbor viruses hemagglutinins are not as easily demonstrable as the hemagglutinins from the other two subdivisions, it is not, in general, difficult to prepare agglutinating antigens with most members of the arthropod-borne group The usual source of hemagglutinin, infected mouse brain or, in certain instances, infected mouse serum, contain inhibitory substances which may inhibit or mask the reaction and must be removed In addition, the pH range (6 0 to 7 2) at which the antigens are active is narrower than with the other two subdivisions.

Inhibition of hemagglutination is not always due to specific antibody but under some circumstances may be due to nonspecific factors As concerns the myxoviruses, nonspecific inhibitors to these agents are found in a wide variety of biologic substances, e g , fluid from ovarian cysts, egg white, salivary glands, human urine, serum, etc , and appear to be mucoproteins Since the concentration of inhibitors in serum may be so high as to mask

inhibition due to specific antibody, and since its mere presence frequently is sufficient to give rise to misleading diagnostic results, destruction of the inhibitors not infrequently becomes a requisite in diagnostic work. The inhibitors to the myxoviruses can be destroyed by means of receptor destroying enzyme (RDE) from *V. cholerae* filtrates, or by trypsin or potassium periodate.

The inhibitors of the arbor viruses appear to be lipoproteins and can be removed from the serum by extraction with acetone or chloroform, or by adsorption to substances such as kaolin. Development of inhibitory antibodies during the course of infection can be demonstrated with these agents; however, the presence of group cross-reactions often renders the interpretation of the results difficult concerning the specific agent or agents involved in the infection. Where the HA and HI tests have been most helpful is as a screening procedure for sera and as a means for identification and classification of these viruses. By means of this test, the arbor viruses can be classified into at least 3 immunologic groups (Chap. 12). Group A, for example, contains eastern, western and Venezuelan equine encephalomyelitis viruses, Semliki Forest virus, Sindbis, Mayaro, etc., whereas Group B contains Japanese B, St. Louis, Murray Valley encephalitis viruses, Russian spring-summer encephalitis virus, yellow fever virus, dengue virus, etc. In Group C, there are certain viruses (Chap. 19) about which relatively little is known. With a number of the arbor viruses, it has not been possible as yet to demonstrate the existence of hemagglutinins, but there is a suggestion that additional immunologic groups may exist. It is to be recalled that the demonstration of specific or group inhibiting antibodies requires the removal of nonspecific inhibitors from the sera under test. This type of nonspecific inhibitor has been found in the sera from all animal species so far investigated. In this respect, arbor viruses do not differ greatly from certain myxoviruses (see above).

For detailed information regarding the technics that are currently used for the identification and the classification of the arbor viruses the reader is referred to a forthcoming publication by Clarke and Casals (1958).

Indirect Hemagglutination

Certain viruses which, by the usual technics for the demonstration of direct hemagglutination, appear to possess no hemagglutinative properties can be made to agglutinate erythrocytes by an indirect method. Basically, the method depends upon the adsorption of reactive material (whether elementary bodies or viral antigens is uncertain) onto the surface of an essentially inert carrier particle, in this case the erythrocyte. When the specific complementary reagent, namely, antibody, is added, visible aggregation of the carrier particle occurs. Thus, herpes simplex virus can be adsorbed onto sheep erythrocytes whose surface has been altered by prior treatment with tannic acid. When such virus-coated cells are exposed to specific immune serum, hemagglutination occurs (Scott et al., 1957). The method can be used for the quantitation of antibody in serum, and it should be noted that the action of the immune serum is to cause hemagglutination and not, as is true in the direct type of test, to inhibit hemagglutination. A similar hemagglutination test has been described for the quantitation of adenovirus antibodies (Friedman and Bennett, 1957).

Erythrocyte Sensitizing Substance (ESS)

Chang (1953) and Chang et al. (1953) described the isolation of a serologically active heat-stable antigen from typhus fever rickettsiae and subsequently encountered a similar antigen in rickettsiae of the Rocky Mountain spotted fever group (Chang et al., 1954). The serologically active material, designated the erythrocyte sensitizing substance, or ESS, renders human group O erythrocytes susceptible to agglutination by specific immune sera.

The hemagglutination of ESS-treated erythrocytes, the so-called anti-ESS test, may

over the complement-fixation test in that it is not only simpler to perform but also ESS antibodies appear earlier in the course of infection than do complement-fixing antibodies The advantage of the test over macroscopic rickettsial agglutination methods lies in the very small amounts of antigen it requires The test is also reported (Chang et al, 1953) to be superior to the Weil-Felix test, both in its specificity and in its ability to detect antibodies in the sera of patients with Brill's disease (such sera often contain no demonstrable agglutinins to proteus OX-19) With respect to infections by rickettsiae of the Rocky Mountain spotted fever group, the anti-ESS test possesses similar advantages over the conventional diagnostic methods

ESS does not react in direct complement-fixation or precipitin tests, and antibodies against the ESS of epidemic typhus rickettsiae appear to be distinct from those which

cytes. This suggests that ESS and soluble antigen are closely related and raises the possibility that ESS arises from degradation of soluble antigen

The presence in the tissues of mice infected with *R mooseri* of an antigen apparently related to ESS has been described recently (Downs et al, 1955) This antigen, when added to murine typhus antisera, inhibits their ability to agglutinate ESS-treated cells The antigen is heat-stable, does not fix complement and resembles ESS in a number of ways but, unlike ESS, it does not sensitize erythrocytes to the action of specific immune sera

COLD HEMAGGLUTININS AND STREPTOCOCCUS MG AGGLUTININS

These agglutinins appear in the sera of a considerable proportion of patients with primary atypical pneumonia Their presence is diagnostically significant, although neither has any specific relationship to the disease

Primary atypical pneumonia represents a clinical and roentgenographic syndrome of diverse etiology (Chap. 29). Clinically indistinguishable cases may be produced by bacteria, fungi and especially by viruses and rickettsiae of established identity, e.g, influenza A and B, ornithosis and lymphocytic choriomeningitis viruses, *Coxiella burnetii*, etc However, this heterogeneous group of agents is responsible for only a small proportion of the cases clinically and roentgenographically regarded as primary atypical pneumonia. *In addition, patients infected with these agents develop specific antibodies to them but do not develop cold agglutinins or streptococcus MG agglutinins* When the pneumonitides due to these and similar causes are removed from consideration, there remains a quite appreciable residuum whose etiology has been ascribed to several agents, all presumably viral and different from each other (Chap 29).

As a consequence of recent work, primary atypical pneumonia can be divided into 3 groups. The first group consists of cases in which an adenovirus, generally type 4 or type 7, is etiologically responsible, these patients do not develop cold or MG agglutinins. The second category is comprised of cases which develop cold or MG agglutinins, but from which no virus has been isolated, or at least is generally accepted as the responsible etiologic agent The third category consists of cases not classifiable into either of the other 2 groups

Cold agglutinins derive their name from the fact that they possess the capacity to agglutinate human group O erythrocytes at icebox temperatures but not at body tempera-

glutinin is indicated by the fact that it is encountered in a variety of diseases, e g, trypanosomiasis, hemolytic anemias, blackwater fever, etc Cold hemagglutinins may also be encountered in a variety of common respiratory diseases, but in low titer; primary atypical pneumonia appears to be the only respiratory disease in which high titers of cold hemagglutinins are often present The hemagglutinin is generally detectable in the serum during the second week of the disease and reaches maximal titers during the third

or fourth week, gradually declines thereafter and finally disappears As with other viral serologic tests, a 4-fold or greater rise in titer [illegible]

hemagglutinins in a patient's serum should not be regarded as pathognomonic of primary atypical pneumonia

The frequency with which cold hemagglutinins are demonstrable in primary atypical pneumonia averages about 50 per cent (Horsfall, 1947, Finland and Barnes, 1951), the reported frequencies ranging from as low as 30 per cent to as high as 90 per cent Since the titer is generally proportional to the severity of the disease, the disparity in the frequency with which the hemagglutinins have been encountered by various observers may result from differences in severity of the illnesses studied

Streptococcus MG is a nonhemolytic streptococcus which was isolated from the lungs of fatal cases of primary atypical pneumonia by Thomas et al (1945) There is no evidence to incriminate streptococcus MG as the causal agent of primary atypical pneumonia, but it is of interest that during recovery from this disease, many patients develop agglutinins against this organism This streptococcus has been encountered in the respiratory tract of normal individuals It is found not infrequently in patients with acute respiratory disease without a pneumonic component, but it is found much more commonly in cases of primary atypical pneumonia than in other types of acute respiratory disease Similarly, although agglutinins to this streptococcus may be found in conditions other than primary atypical pneumonia, rises in titer have been observed almost entirely in primary atypical pneumonia The agglutinins appear about the second or third week after onset of illness and attain maximum titers during the fourth or fifth week A 4-fold or greater rise in titer is of diagnostic significance, although the presence of a high titer, i e, 1 32 or greater, in a single convalescent phase serum specimen affords presumptive positive evidence of primary atypical pneumonia As is true with cold hemagglutinins, the titer of MG agglutinins attained is correlated with the severity of the disease While many patients develop both cold hemagglutinins and MG agglutinins, an appreciable number develop one but not the other Consequently, it is desirable that sera be tested for the presence of both types of agglutinin

RICKETTSIAL AND VIRAL TOXINS

Clinical descriptions of patients with certain viral and rickettsial diseases, and especially the latter, frequently include remarks upon the toxic appearance of the individual. Experimentally, this clinical impression finds justification in the clear demonstration within recent years that toxic substances are elaborated by, or form an integral part of, certain rickettsiae and viruses. These toxic substances, or toxins as they are generally referred to, are demonstrable only in preparations with very high concentrations of infectious organisms Up to the present time, it has not been possible to separate the toxins from the living micro-organisms.

In 1940, Gildemeister and Haagen reported that mice inoculated intraperitoneally with yolk-sac suspensions heavily infected with murine typhus rickettsiae (*Rickettsia mooseri*) died within 4 to 20 hours Others have reported similar results to follow inoculation with epidemic typhus (*R prowazeki*) or scrub typhus (*R orientalis*) rickettsiae (Cox, 1953) The rapidity with which death ensues indicates that a toxin and not infection is responsible This is supported by the observation that animals that survive the acute illness produced by the original heavy inoculum remain well for some days and then develop the usual signs of infection and die

Attempts to separate a toxin from the infectious particle have thus far been unsuccessful, apparently because of the highly labile nature of the toxin The toxin can be preserved by storage of the infectious suspensions on dry ice, but storage at icebox temperatures leads to marked losses in potency over a matter of days The toxin can be destroyed by heating (56° C), by the addition of diethyl ether or by the addition of formalin (0 3 to 0 4%)

Bengtson et al (1945) showed that addition of formalin to suspensions of epidemic typhus rickettsiae destroyed the lethal capacity of the toxin but preserved its immunogenicity, since inoculation of such noninfectious material into man or guinea pigs elicits an antitoxin response (Topping et al ,

1945) Conversion of toxin into a toxoid by formalinization has also been shown with murine typhus rickettsiae. Similarly, several viruses of the psittacosis-lymphogranuloma venereum group have been found to retain their capacity to produce antitoxin after inactivation. Inactivated preparations of influenza A and B viruses also retain their immunogenic capacity to protect mice against the toxic action of fully infectious preparations (Henle and Henle, 1946a, 1946b).

In general, the antitoxins elicited by rickettsial and viral toxins are highly specific. The antitoxins produced against the rickettsiae of

capacity of each antitoxin for the heterologous toxin However, the toxin of the Gilliam strain of scrub typhus rickettsiae is so very highly specific that it is neutralized by its homologous antiserum but not by antisera to heterologous strains of *R. orientalis* (Smadel et al, 1946) An analogous situation exists with respect to the viruses Thus, the toxic factors of the influenza A and influenza B viruses produce antitoxins which have no neutralizing effect on the toxins of other myxoviruses However, certain viruses within

examined 27 viruses of the psittacosis group and found them classifiable into 6 groups on the basis of toxin neutralization tests in mice. Of these 27 strains, only the toxins and the corresponding antitoxins of the Louisiana and the feline pneumonitis strains were specific; the remaining 25 strains were divisible into 4 groups which showed antigenic overlapping

The existence of toxins has been clearly shown for the rickettsiae of epidemic typhus (*R. prowazeki*), murine typhus (*R mooseri*), scrub typhus (*R. orientalis*), and Rocky Mountain spotted fever (*R. rickettsii*) (Bell

disease, mumps and eastern and western equine encephalomyelitis viruses (Cox, 1953).

The toxins produced by the rickettsiae and by the psittacosis-LGV group of viruses resemble the bacterial exotoxins rather than the bacterial endotoxins The toxic factors of *R prowazeki* recently described by Olitzki et al (1946) and considered by them to resemble the endotoxins of gram-negative bacteria appear to be unrelated to the toxic materials mentioned above, and highly lethal for the mouse.

The symptomatology and the histopathologic changes produced by the mouse-lethal toxins associated with different rickettsiae are quite similar. Within 1 to 2 hours after inoculation, the mice develop weakness and labored breathing, succeeded by prostration and convulsive seizures; most animals die within 1½ to 3 hours after inoculation, but death may be delayed for as long as 18 hours, seldom more. The symptoms produced by the viral toxins are similar, but death may occur from within 1 up to 24 hours, and sometimes longer, depending upon the virus

Mice which succumb to rickettsial toxins show congestion of the visceral blood vessels in general, and of the small intestine in particular. In some instances, the gut appears hemorrhagic. Frequently, however, the mucosa of the small bowel is covered with a yellowish fluid, and there is marked dilatation of the blood vessels in the villi (Neva and Snyder, 1952) Mice which die early after inoculation with a viral toxin show a gross

thrombi in the glomerular capillaries. The liver may show some focal necrosis, but usually the lesions consist of foci of damaged cells containing fat droplets In mice which die at the later stages after inoculation, pulmonary hemorrhage or edema is seldom seen, but a pronounced focal necrosis of the liver is generally present (Rake and Jones, 1944, Henle and Henle, 1946b, Fastier, 1952).

Studies on viral and rickettsial toxins have been conducted almost entirely in mice, although in some instances other species may be used in place of the mouse In some cases the toxic effect of an agent has been demonstrable by the effect produced in animal species other than the mouse Neva and Snyder (1952) reported that the white rat reacts to the toxins of typhus rickettsiae in much the same way as does the white mouse; in addition, the lesions as described above for the white mouse were also seen in the rat, in which they were somewhat more marked The importance of species for the demonstra-

tion or the detection of toxic activity is indicated by the fact that the white rat is approximately 5 times more resistant to the toxin of R. *mooseri* than to the toxin of *R. prowazeki* (Neva and Snyder, 1952) and also by the fact that the cotton rat, unlike the white rat, fails to react to the toxin but succumbs to infection (Neva and Snyder, 1952)

Intra-ocular inoculation of the rabbit with type A or type B influenza virus results in corneal opacity without demonstrable multiplication of the virus; the toxic effect can be prevented by neutralization of the toxin with specific antiserum (Evans and Rickard, 1945) Corneal opacity similar to that produced by the toxin of the influenza viruses can also be produced by intra-ocular inoculation of the eastern and western equine encephalomyelitis viruses (Evans and Bolin, 1946) and mumps virus (Bolin et al, 1950) Intravenous inoculation of the rabbit with influenza virus (Wagner et al, 1949) or western equine encephalomyelitis virus (Fastier, 1952) elicits a febrile response and a leukopenia which would appear to be manifestations of viral toxicity

At the present time, little is known about the nature of the toxins and of their role, if any, in the pathogenesis of disease The toxins have not been utilized for viral or rickettsial diagnostic purposes, but they have been applied to the standardization of typhus fever vaccines (Cox, 1953) and have assisted in some instances in the classification of related viruses (Manire and Meyer, 1950)

SOLUBLE ANTIGENS

During the course of certain viral and rickettsial infections, there are elaborated substances which are serologically active and highly specific for the infecting agent Since these reactive materials are noninfectious and are separable from the infectious agent itself, they are referred to as soluble antigens In its broadest sense, the term includes all the serologically active materials—complement-fixing, precipitating, hemagglutinating, etc, antigens—that are readily separable from the infective viral or rickettsial bodies by simple physical technics In a restricted sense, and the one in which the term is usually employed, the designation soluble antigen or S antigen is understood to refer to complement-fixing material separable from the infective particles

Soluble antigens are smaller in size than the rickettsial or viral agents with which they are associated Obviously, the occurrence of such antigens is recognized most readily among the larger and more complex viruses and the rickettsiae In dealing with viruses of progressively smaller size, it becomes increasingly difficult to determine whether the observed reactivity is attributable to a soluble antigen or to the viral particle per se. Such difficulties are exemplified by yellow fever, in which it has not proved to be possible to determine whether the noninfectious, serologically specific substance found in this disease (Hughes, 1933, Lennette and Perlowagora, 1945) is a soluble antigen within the accepted meaning of that term.

The existence of soluble antigens was first shown by Craigie (1932) in connection with vaccinia virus The antigen, demonstrable by its activity in precipitation and complement-fixation tests, could be separated from the elementary bodies by filtration or by high-speed centrifugation The soluble substance was named LS antigen when it was found to

extractable from elementary bodies (Smadel et al., 1942) and, like the LS antigen, reacts in precipitin and complement-fixation tests Animals inoculated with these antigens produce complement-fixing and precipitating antibodies but do not develop neutralizing antibodies nor do they develop resistance to infection with the virus

Since Craigie's original observations, soluble (complement-fixing) antigens have been described in association with a number of viruses and rickettsiae As is brought out in the chapters dealing with specific diseases, soluble antigens have been described for the psittacosis-lymphogranuloma venereum group of viruses and for the viruses of lymphocytic choriomeningitis, influenza A and influenza B, mumps, etc, and for the rickettsiae of epidemic and murine typhus, Rocky Mountain spotted fever and boutonneuse fever, rickettsialpox and scrub typhus

The association of soluble antigens with rickettsiae was not demonstrated until 1942 (Smadel, 1948) It is of interest that the soluble antigen of *R. prowazeki* differs from

that associated with vaccinia virus, for example, in that the former possesses many of the immunogenic properties of the intact rickettsial body, and consequently it is desirable to include it in vaccines. (A soluble *immunizing* antigen obtained by some disruption of the rickettsiae has been described for Q fever [Colter et al, 1956] No information is available on its serologic reactivity)

The soluble antigens of *R prowazeki* and *R mooseri* are virtually indistinguishable, hence, when used in diagnostic complement-fixation tests, they do not differentiate between infections due to these organisms The cross-reactive materials or antigens can be removed by washing the rickettsial suspensions, for a time, the washed organisms will give essentially type-specific fixation. Disruption of *R prowazeki*, for example, releases a nucleoprotein which reacts as a comparatively type-specific antigen in the complement-fixation test In the presence of proteolytic enzymes, however, type-specificity is destroyed, and the antigen acquires group-specific reactivity (Chambers et al, 1950)

In a similar way, the rickettsia of Rocky Mountain spotted fever shares a soluble antigen in common with boutonneuse fever and with rickettsialpox

Information concerning the nature and the properties of soluble antigens is still relatively meager, and perhaps the most comprehensive body of information available on soluble antigens at the present time is that in connection with influenza viruses

The soluble or S antigen of influenza virus is present in high concentrations in infected tissues Infected cells which release virus release comparatively little S. The antigen is separable from the viral particle by high-speed centrifugation or by adsorption of the elementary bodies onto red cells, since it has a smaller particle size than the elementary body, it is not readily sedimented Also, unlike the virus, the antigen is not adsorbed to red blood cells The S antigen is characterized by possessing *only complement-fixing activity*, whereas the elementary bodies of the virus possess some complement-fixing activity in addition to other properties such as infectivity, hemagglutinating capacity, toxicity, interfering capacity, etc.

The viral, or V, antigens are serologically distinct from the S antigen (Wiener et al, 1946). The S antigen is type-specific, since S antigens obtained from various strains of influenza A virus are identical but are distinct from those obtained from influenza B virus strains (Lennette and Horsfall, 1941; Kirber and Henle, 1950). The V antigens also show cross-reactivity within the virus type but also possess marked strain-specific components within the mosaic that makes up the antigen. As mentioned earlier, the V antigen, as represented by washed elementary bodies, may also contain some S antigen (Lennette and Horsfall, 1940, Kirber and Henle, 1950).

It has been suggested (Fulton, 1949; Kirber and Henle, 1950) that the S antigen is not an integral part of the viral particle but is a by-product resulting from the pathologic action of the virus on the cell Other data, and especially more recent findings, indicate that the S antigen is an integral part of the influenza virus particle (Hoyle, 1952) Hoyle (1952) reported that when the elementary bodies of influenza virus are treated with ether, they disintegrate with the liberation of two types of smaller particles, namely, soluble antigen and hemagglutinin. The experimental work of Lief and Henle (1956a, 1956b) also indicates that the S antigen forms an integral part of the elementary body; they found that washed viral suspensions free of detectable S yielded high titers of S after exposure to ether, which suggests that the viral particle contains large concentrations of S Also pointing to the internal location of the S antigen is the finding that standard virus preparations yield uniform amounts of antigen on ether treatment (Lief and Henle, 1956a), incomplete virus releases less antigen than does complete virus, the amount of S liberated decreasing with increasing incompleteness of the viral moiety (Lief and Henle, 1956b), and that the release of S antigen is associated with nearly complete destruction of infectivity

Recent evidence indicates that the S antigen of influenza virus, and also of fowl plague virus (Schaffer and Zillig, 1954), is a ribose nucleoprotein (Hoyle, 1952; Ada and Perry, 1954; Paucker et al, 1956).

Principles and Methods of Epidemiology

INTRODUCTION

By derivation, epidemiology would seem to be concerned with the explanation of epidemics of disease in human populations While this definition still obtains in part, naturally with the advance in biologic and medical sciences the field included under epidemiology has broadened considerably (Frost, 1927, Maxcy, 1941, Clark and Leavell, 1953, Taylor and Knowelden, 1957) An epidemic is commonly a sudden increase in the prevalence of a disease which is more or less constantly present or endemic in a community To explain the sudden increase it is necessary to *understand the factors which determine the* usual or interepidemic levels of prevalence and the characteristic distributions which the disease manifests in human populations

The widening horizon of the biologic universe has extended use of the term "epidemiology" to the study of disease in animal populations and plant life Although "enzootic" and "epizootic" have been used by veterinarians to describe the level of prevalence of diseases in animal populations, it is now considered good usage to refer to the epidemiology of cattle plague or of foot and mouth disease While it is etymologically correct to use "epiphytic" *to refer to an outbreak of* infectious disease in plants, a modern plant pathologist may prefer to describe his observations on the stem rust of wheat under the title of epidemiology Such usages are justified by the derivation of the word "epidemic," which, literally translated from the Greek, *means "upon the population"* The population may be composed of people, animals, birds, fish, plants, or whatnot Moreover, while in its early history epidemiology was largely concerned with infectious diseases, it has been found profitable to make a similar approach to the understanding of diseases of unknown etiology, conditions due to nutritional deficiencies, to mental disorders, relationship of excessive smoking to lung cancer, to blood pressure readings, to abnormal cell growth, and even to casualties caused by physical or chemical agents, accidents, etc

Thus, usage has extended the meaning of epidemiology beyond its original limits to designate not merely the doctrine of epidemics but a science of broader scope in relation to the mass-phenomena of diseases in their usual as well as their epidemic occurrences The subject is pursued here with homocentric bias, since our concern is primarily with human welfare For present purposes, therefore, *epidemiology is defined as that field of medical science which is concerned with the relationships of the various factors and conditions which determine the frequencies and the distributions of an infectious process, a disease, or a physiologic state in a human community* It seeks to advance rational conceptual schemes of causation of various ills that afflict mankind, medically speaking To the extent that this body of knowledge is advanced and valid, it becomes possible for appropriate community agencies to take effective meas-

channels to regional lymph nodes, after which it must travel by way of the lymphatics in a stepwise multiplication and invasion, bypassing the defensive barriers in the phagocytic and serologic activity of the host tissues, ultimately to gain admission to the general circulation and select the organs or tissue cells for which it has a predilection and in which it can multiply, as is the case in such diseases as infectious hepatitis. Thus, the incubation period may be a matter of hours, days, weeks, or even months, but for any particular disease its length is relatively constant and predictable. However, as with any other measurable biologic attribute, the incubation period of a specific disease manifests a constant range of variation. Frequency distributions of incubation periods bear a resemblance to the normal curve with a slight skewness, rising more abruptly on the short side of the mean and tailing off on the long side. As pointed out by Sartwell (1950), the degree of variation in relation to the magnitude of the mean has a constant statistical pattern, no matter whether the unit of time be hours, days, weeks or months. The range of the incubation period is an important epidemiologic characteristic for each disease. It determines the time interval necessary for comparison with dates of onset of cases in judging whether an outbreak is due to a common vehicle of dissemination or not, and, when an epidemic is due to transmission from person to person by contact, it determines the rapidity of spread of a disease through a population.

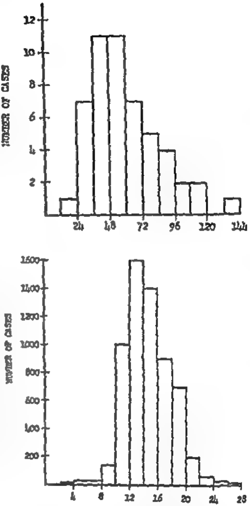

FIG 50 Frequency distributions of incubation periods (*Top*) Epidemic of food-borne streptococcal sore throat (scarlet fever) (in hours). (*Bottom*) A series of cases of serum hepatitis following administration of icterogenic lots of yellow fever vaccine (in weeks) (Sartwell, P. E., 1950, Am J Hyg *51*, 311)

HOST-PARASITE INTERACTION

The second critical stage in the host-parasite relationship mentioned above is the one which may give rise to symptoms and signs of illness by which a disease is recognized. The host reaction varies both in severity and duration. A case of an infectious disease is a host reaction of sufficiently characteristic intensity and duration to permit clinical diagnosis. Reactions which are less intense and of shorter duration are called *abortive* or *suspected* cases, the pattern being too indefinite or protean in nature to permit clinical diagnosis, except in association with *frank* cases. When the subjective and objective symptoms are so slight as to pass unnoticed, the host is said to suffer from an *inapparent* infection. Infections which are below the threshold of clinical recognition are grouped together as *subclinical*. They can be identified by laboratory procedures such as cultural recovery of the infecting micro-organism from the host's tissues, change in the response of the skin to specific antigenic material, or change in a serologic reaction from a negative to positive. It is at least theoretically possible that an

ures directed toward prevention, control or eradication As defined, the field is a broad one.

With the advances in the field of general biology and the collateral medical sciences during the past century, the principal concept of infectious disease gradually became evident It was *comprehensively formulated* by Theobald Smith (1934). ***Infectious disease is a manifestation of parasitism*** Simple though this concept seems today, its formulation marked an important transition The medical explanation of an infectious disease in man broadened to become a biologic one *Finally, it was realized* and accepted that infection should not be set apart as peculiarly within the province of human medicine but was viewed in its natural relationships as an expression of the eternal struggle of living things for food by predation, or parasitism, for shelter and for propagation of their kind. *More particularly* it is the reaction between one of the higher forms of life to the invasion of its tissues by some species of microparasite This conception carries with it implications that are fundamental and far-reaching It affords a framework or pattern into which endless scattered observations can be fitted Explanation of epidemics can then be sought in host-parasite relationships and the environmental factors which modify them For present purposes and ideas, discussion is centered on the principles of epidemiology as applied to understanding and control of viral and rickettsial infections

HOST-PARASITE RELATIONSHIPS

As a result of centuries of host wanderings, mutation and selective adaptation, the viruses and the rickettsiae considered in this book have in some degree become established in the biologic orbit of man and are responsible for some of his ills Their potentialities range from those which only rarely and inadvertently invade his tissues to cause an occasional sporadic case of a rare disease (such as Q fever) to those which are dependent upon human *tissues for their continuous propaga-* ... *to epi-* ...ons and ...ortance of each viral and rickettsial species to man has been determined by a few biologic principles to which only brief reference is made

Man may be an obligate, a principal or an occasional host species, according to the degree of success which a particular species of parasite has in passing through *4 critical stages in relationship to him* A *micro-organism may become completely dependent upon man* for its survival if it is continually successful (1) in finding entrance into his body through its proper ***portal of entry***, whether it be the mucous membrane of the respiratory, the alimentary or the genito-urinary tracts, or the skin by means of trauma or insect bite: (2) *in reaching the particular organ, tissue or* cells in which nutritive conditions are favorable for ***multiplication***. (3) in making an exit from the body in excretions, secretions, or by blood-sucking insects. (4) in surviving under the conditions of the external environment, or in an insect vector, a sufficient time to reach a new susceptible host *To the extent* that it is unsuccessful in maintaining chain passage through these 4 critical stages in human populations and their environment it must be able to utilize other host species or survival mechanisms Thus, one of the first requisites *of a rational explanation of* the behavior of an infectious disease in a human population is to understand to what extent man as a host bears responsibility for the continuous propagation of the causative microparasite (contagious) or shares this responsibility with other species—animal, bird or insect (noncontagious infection).

INCUBATION PERIOD

The first stage in infection is the incubation period, i e , the interval of time from primary invasion through the skin or the mucous membranes to the onset of symptoms of the disease *Its length depends upon the peculiarities of* each particular host-parasite relationship. It is short, a matter of days, when the microparasite has more or less direct access to the tissue in which the primary multiplication takes place, as in certain air-borne infections caused by microparasites which multiply in *the epithelial cells lining the respiratory tract;* influenza is an example *It is longer in those* infections in which the microparasite is unable to multiply at the site of entrance into the body but must make its way through lymph

only with the species of microparasites but frequently with different strains of the same species

SUCCESSFUL PARASITISM

Successful adaptation of a species of microparasite to the human host does not imply a high order of pathogenicity Rather the contrary is true Success for a parasite as for any other living organism, can be measured only by the size of the population of its kind and its ability to survive and maintain these numbers in a constantly changing natural universe There is no advantage if its host sickens and dies, since dissemination of its progeny accordingly becomes limited and soon ceases The opportunities for scatter and chance of productive contact are increased in proportion to the length of time it can continue to multiply and find easy egress in large numbers from a host which is ambulatory and gregarious Accordingly, a high case-fatality rate may be a disadvantage to survival of a parasitic agent Conversely, a low ratio of clinical to subclinical infections and a long duration of the infectious period tend to ensure wide dissemination The microparasites best adapted for survival are those which cause infection with the least inconvenience and injury to the host and create only a low-grade immunity of short duration, a notable exception is rabies

COMMUNITY SUSCEPTIBILITY

A human community is made up of a number of individuals who vary not only in their genetic capacity to react but nearly always in previous experience with the predominant strains of the particular species of microparasite or its close relatives Some individuals have acquired a complete immunity some a partial immunity, some none The proportion of a population at any one time which has little or no immunity determines the theoretical *susceptibility status* or the mass susceptibility of a community for the infectious disease which a specific microparasite causes If a micro-organism is commonly prevalent in a community, the proportion is a constantly changing one as susceptibles are infected, develop immunity and recover If the natural immunity conferred by an infection is durable then susceptibility decreases with age, and the age distribution of cases is consequently that of a *children's* disease If the immunity conferred is temporary, as with many acute respiratory infections, the same individual may be reinfected, and consequently the disease attacks all ages—adults and old people as well as infants and children Thus, community susceptibility has an age distribution, which is specific for each infectious agent, the range of which is indicated by the reciprocal, the age distribution of cases of the disease which it causes provided that exposure is a common experience

With some infections it is possible by means of a skin test or a serologic test for specific antibodies, obtained on a representative sample of persons, to establish the immunity status of a community A common example of the former is the use of the Schick test to determine a community's susceptibility to diphtheria An illustration of the latter is the extensive use of the neutralization test or complement-fixation test as an indication of past infection with yellow fever virus in mapping out the geographic areas in which it is or has been prevalent By ascertaining the correlation of positive sera with age it is possible to discover whether the disease has been prevalent recently or to determine the period of time which has elapsed since the population was last exposed Thus with adequate representation of all ages in the samples of sera tested, if the positive sera were distributed randomly with regard to age and indicated infections in early life, it could be inferred that the exposure was continuing If, on the other hand, the positive sera came only from persons beyond a certain age as for example, beyond the age of 20, it could be inferred that the infection had not been prevalent in the area for the past 20 years

TRANSMISSION

The qualitative variation taking place within the microparasitic and host populations, and the variations in conditions which affect their interrelationships with each other and

infection may occur without demonstrable reaction on the part of the host, i.e., a symbiotic or a saprophytic relationship, but there is a difference of opinion as to whether the word infection should be used to describe such a condition

INFECTIOUS PERIOD

In clinical medicine, interest is centered upon a patient during the period that he or she is more or less incapacitated by the disturbance of physiologic functions caused by the invasion of a pathogenic micro-organism, that is, from the onset of symptoms to clinical recovery or to a fatal issue In epidemiology, interest must be broadened to include the whole duration of the host-parasite relationship, that is, from the time of the infective exposure until the microparasite is suppressed or eliminated from the host's body Of particular importance is the *infectious period*, the time or times during which the microparasite progeny are making an exit or are potentially available for transfer to a new host

CARRIERS

As early as 1890, Escherich noted that the infectious period of diphtheria was not necessarily coincident with the clinical course but that diphtheria bacilli might persist in the throats of patients during convalescence In 1892, Guttmann, Rommelaere and Simonds noted that cholera vibrios might be recovered from the feces during convalescence Credit probably belongs to Koch (Winslow, 1943) for grasping the important fact that cases which could be diagnosed clinically were not alone responsible for the spread of contagious diseases In his studies of cholera in Germany, during the winter of 1892-93, he noted that some cases were so mild that they escaped recognition and indeed could be detected only with the aid of a bacteriologic investigation The term "carrier" thus includes two classes. First, there are those who are about to have, or have already had, a clinical attack; they are sometimes designated as *incubatory*, *convalescent* or *chronic* carriers. Second, there are those who are suffering from a subclinical or asymptomatic infection, the so-called *healthy* carriers It is important to distinguish between these two classes, and for the purposes of this discussion, the second class of carriers are included in the designation *subclinical* or *inapparent* infections.

PATHOGENICITY

The characteristics of a clinical reaction and the ultimate issue of an infectious process in death or recovery are determined by the balance between the devices of aggression of a specific species of microparasite and the mechanisms of defense of the host species, potentialities for both of which are transmitted genetically The technical detail involved in classifying an individual as susceptible or immune is developed by what is known of pathogenesis and immunology.

The pathogenicity of a microparasite species for a human host population cannot be measured experimentally in animals It is indicated only by observations on the experience of *human beings exposed to a particular infection* under natural conditions To the extent that infection may result in recovery or death, pathogenicity is roughly indicated by the proportion of attacks which are fatal Stated in different words, it is a ratio between cases and deaths (the percentage of cases which are fatal) or the *case-fatality ratio* of a disease This ratio may be affected in a considerable measure by nonspecific conditions which affect the host population, such as starvation, lack of proper medical care, secondary invasion by other micro-organisms, and other factors To the extent that infection may result in a residual of impaired function, pathogenicity may be indicated by the proportion of cases which exhibit paralysis or other complications Finally, and more important, it is possible, in dealing with many infectious diseases, to estimate the proportion of persons infected with a particular microparasite who manifest a characteristic clinical reaction to those who do not, *the ratio of clinical to subclinical infections*. For example, in measles it is of the order of 19.1; on the other hand, in poliomyelitis it has been estimated to be of the order of 1:100 Such ratios vary not

(1) A cause-specific death rate or mortality rate:

$$\frac{\text{Number of deaths from a specific disease during a calendar period}}{\text{Average population present during same calendar period}} \times 100\,^{*}$$

(2) A case rate, attack rate or morbidity rate.

$$\frac{\text{Number of cases of a specific disease developing during a calendar period}}{\text{Average population present during same calendar period}} \times 100\,^{*}$$

(3) Prevalence ratio

$$\frac{\text{Number of cases of a specific disease existing at a particular time}}{\text{Population present or surveyed at that time}} \times 100\,^{*}$$

(4) Incidence rate

$$\frac{\text{Number of events in the population at risk during the specified time}}{\text{Mean population at risk of event during specified time}}$$

deaths, cases or infections (numerator) were discovered and recorded, and the clinical and laboratory criteria employed in diagnosis and classification The soundness of inferences drawn from biostatistical material can never exceed the level of accuracy of the original data

To represent [illegible] in [illegible] a h[illegible] hap[illegible] periods of time For adequate expression, the numerator of the fraction then should preferably be the number of *new* cases or *new* infections which are reported, or have their onset, or are discovered or are admitted to a clinic in successive days, weeks, months or years If the number of host population (denominator) remains relatively stable during the period under consideration, the number of new cases or new infections alone will suffice to indicate the course of events without calculating rates Thus the *incidence* of disease, or an *incidence rate*, is a dynamic concept It reflects changes in the frequency with which the microparasite is spreading and gaining access to new susceptible individuals, and, accordingly, the increase or decrease in microparasitic population

An accurate statement of incidence must take into account not only the number of new cases (numerator) but the total number of new individuals at risk (denominator) in each successive time period It makes a great deal of difference whether it is a closed or an open universe, i e , whether the population is composed of the same, or approximately the same, individuals throughout the period of observation or whether the individuals in the population are changing through immigration and emigration For example, an incidence of cerebrospinal meningitis in one army camp 10 times greater than in another when expressed on the basis of "cases per thousand strength per year" may be due to the fact that in the latter the personnel is permanent, while in the former it is changing periodically through the arrival of recruits and the departure of graduates from a course of training, so that 10 times as many individuals are at risk of infection during the course of a year.

A prevalence ratio (3) is, properly speaking, a static concept It represents how much

* This rate may be expressed on the basis of any population unit considered to be appropriate—per cent, per 1,000, per 10,000, per 100,000 The time unit chosen, whether it be hours, days, weeks, months, or years, is also varied according to circumstances

with the environment, results in quantitative changes The size of the microparasitic population depends upon the rapidity of passage from person to person and the accumulated proportion of persons harboring the infectious agent at any one time. This is determined not only by the proportion of susceptibles but by the opportunities for progressive transfer to new hosts, i e , the *exposure* or *contact rate* This rate is affected by a variety of conditions, *depending upon the requirements for transmission* For those diseases which are transmitted from person to person by some form of direct or indirect contact, the importance of the degree of crowding, or density of population, as determined by living in urban or rural areas, in private homes, in institutions, or in military installations, is obvious For those diseases which are transmitted to some extent at least by contamination of food, milk or water, the importance of sanitary conditions and home hygiene is evident For diseases transmitted by insects there are a whole series of conditions which affect the numbers of the vector species, their access to man, and requirements of the microparasite for completing a cycle of development. In every community the ecology is changing constantly with the habits of the people, day in and day out, from season to season, and from year to year

OPERATION OF CHANCE

If an individual in the infectious stage of a disease arrives in a community from which the disease has been absent for some time, what happens will be determined in part by the susceptibility status, in part by exposure or contact rates, and finally by the operation of chance For example, a person may develop measles and, since by chance the contacts immediately exposed are immune, no secondary cases will occur. Or, a second and a third case may occur without further transmission of the disease to susceptibles So the chain of propagation of an infectious agent may *build up or diminish and disappear*, depending on the one hand upon the continuing chance contacts between cases and susceptibles and on the other upon contacts between cases and immunes.

INCIDENCE OR PREVALENCE

The forces which create the dynamic biologic *phenomena of infectious disease are*, in the ultimate analysis, population pressures, i e., the innate impulse of living micro-organisms to multiply and survive by parasitism upon *homo sapiens* and the efforts of the host species to preserve its own integrity The balance between these two forces is fluctuating constantly, just as are the interactions between other living species, as for example, between the carnivores and their herbivorous food sources. When the equilibrium is a relatively stable one, it is manifested by an *endemic* prevalence. When the equilibrium is subject to sudden and violent disturbances, it is manifested by *epidemics* If the balance is in favor of the host, the disease shows a downward trend and tends to disappear If the balance is in favor of the microparasite, the disease tends to increase in prevalence and in certain instances may act as a temporary human population check if it is widely distributed and highly fatal

To facilitate reasoning, it is necessary to express these phenomena in quantitative terms. The basic elements of this statistical methodology are formulae which represent prevalence or incidence. The denominator (number of individuals in the host population) can in many situations be counted or estimated with considerable accuracy. The numerator (number of parasitic micro-organisms) can only be represented indirectly. It is correlated in a rough way with the number of deaths, or cases, or infections caused by a microparasite population. The indices schematically represented on the facing page are used most commonly

Obviously, each of the 4 types of rate has its own implications The one used will depend upon the questions to be answered and the availability of statistical information for the population group or groups under consideration. All are subject to errors of diagnosis and completeness of counting. Basic to effective use in reasoning is an assessment of the approximate validity of a rate. This can be done only when the accompanying text contains a clear statement of the universe of observation (denominator) in place or area, persons and time, the methods by which the

(1) A cause-specific death rate or mortality rate:

$$\frac{\text{Number of deaths from a specific disease during a calendar period}}{\text{Average population present during same calendar period}} \times 100\,^{*}$$

(2) A case rate, attack rate or morbidity rate:

$$\frac{\text{Number of cases of a specific disease developing during a calendar period}}{\text{Average population present during same calendar period}} \times 100\,^{*}$$

(3) Prevalence ratio:

$$\frac{\text{Number of cases of a specific disease existing at a particular time}}{\text{Population present or surveyed at that time}} \times 100\,^{*}$$

(4) Incidence rate

$$\frac{\text{Number of events in the population at risk during the specified time}}{\text{Mean population at risk of event during specified time}}$$

deaths, cases or infections (numerator) were discovered and recorded and the clinical and laboratory criteria employed in diagnosis and classification The soundness of inferences drawn from biostatistical material can never exceed the level of accuracy of the original data

To represent the *shift in balance* or *changes in equilibrium* between a microparasitic and a host population, it is necessary to show what happens in successive periods of time For adequate expression, the numerator of the fraction then should preferably be the number of *new* cases or *new* infections which are reported, or have their onset, or are discovered or are admitted to a clinic in successive days, weeks, months or years If the number of host population (denominator) remains relatively stable during the period under consideration, the number of new cases or new infections alone will suffice to indicate the course of events without calculating rates Thus the *incidence* of disease or an *incidence rate*, is a dynamic concept It reflects changes in the frequency with which the microparasite is spreading and gaining access to new susceptible individuals, and, accordingly, the increase or decrease in microparasitic population

An accurate statement of incidence must take into account not only the number of new cases (numerator) but the total number of new individuals at risk (denominator) in each successive time period It makes a great deal of difference whether it is a closed or an open universe, i e., whether the population is composed of the same, or approximately the same, individuals throughout the period of observation or whether the individuals in the population are changing through immigration and emigration For example, an incidence of cerebrospinal meningitis in one army camp 10 times greater than in another when expressed on the basis of "cases per thousand strength per year" may be due to the fact that in the latter the personnel is permanent, while in the former it is changing periodically through the arrival of recruits and the departure of graduates from a course of training, so that 10 times as many individuals are at risk of infection during the course of a year

A prevalence ratio (3) is, properly speaking, a static concept It represents how much

* This rate may be expressed on the basis of any population unit considered to be appropriate—per cent, per 1,000, per 10,000, per 100,000 The time unit chosen, whether it be hours, days, weeks, months, or years, is also varied according to circumstances

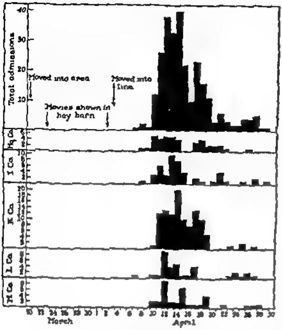

FIG 51 Outbreak of Q fever in the 3rd Battalion, *362nd Infantry*, indicated by daily hospital admissions for units as a whole and for each company (Adapted from Figs 2 and 3, Robbins, F C, Gauld, R L, and Warner, F B, 1946, A fever in the Mediterranean Area Report of its occurrence in Allied troops II Epidemiology, Am J Hyg *44*, 29)

disease there is in a given population existing at a particular time For example, it may be desirable to know how many cases of active tuberculosis, of primary syphilis or of rheumatic heart disease have been identified and are under medical observation in a particular community as of a certain date

COMMON-VEHICLE EPIDEMICS

The word "epidemic" is used most commonly to refer to the sudden or unusual appearance and/or temporary increase in incidence of a disease previously absent or occurring only sporadically in a particular population group and environment It is represented conventionally in a graph by plotting the number of cases (ordinates) by date of report or onset according to the selected time intervals, hours, days, weeks (abscissae) The numbers usually show a regular ratio of increase in successive intervals to reach a maximum and pass over into a similar ratio of decrease so as to describe a more or less symmetrical curve, as illustrated in Figure 51

It is to be noted that the span of time between the minimum and maximum incubation periods varies widely in different diseases For example, in food poisoning due to staphylococcus toxin it is a matter of 1 to 8 hours, in influenza from 1 to 2 days; in measles from 12 to 16 days, in homologous serum jaundice from 2 to 6 months By comparison of this span of time of the disease involved with the period during which the cases included in the outbreak have their onsets, an important inference can be drawn. If the onsets of all or nearly all of the cases fall within an interval no greater than that of the known variation in incubation periods, then it can be assumed that they arose from a nearly simultaneous exposure to a common vehicle of dissemination or to a single source Or, reversing the procedure, if it be known that the group of persons selected by a disease have been together upon only a single occasion, then the common exposure must have occurred at this time and the variation in the incubation periods of different individuals can be calculated. These considerations are illustrated by studies of an outbreak of Q fever among Allied troops in the Mediterranean Area, 1944-45. The following account is paraphrased from the report of Robbins, Gauld and Warner (1946).

In April, 1945, the 3rd Battalion, 362nd Infantry Regiment, with an approximate strength of 900, experienced an explosive outbreak of Q fever A total of 269 soldiers, or almost 30 per cent of the unit, were hospitalized between April 7 to 29, 1945, with an illness diagnosed as primary atypical pneumonia Early in March, the battalion was in the line where the various companies were widely dispersed On March 20 they moved back to rest and bivouacked in an area on the northeastern slope of a ridge about 0 5 mile from Paghana The 4 companies camped in a semicircle about a farmhouse in which the Battalion Headquarters was located and where the headquarters officers lived The farmer and his family remained in the house during this period. The men had pyramidal or pup tents for shelter, and some slept on the ground Some of them used hay from the barn adjacent to the house or straw from a

nearby haystack as bedding This bivouac area was occupied until April 3

While in this location an intensive training program was carried on which included the presentation of numerous training films and motion pictures These films were shown in the loft of the barn adjacent to the farmhouse, and attendance of all personnel in the battalion was compulsory The loft was large enough to accommodate one company at a time, and the companies attended in rotation

The course of the outbreak is shown in Figures 2 and 3 * The first patient was hospitalized on April 7, 4 days after the battalion had moved back into the line and 18 days after it first occupied the area near Pagliana The outbreak was explosive with the peak between April 12 and 14 On April 14 there were 40 hospital admissions from the 3rd Battalion By April 19 the outbreak was almost over, and the last patient was hospitalized on April 29 The total number of cases was 269, with 171 (63%) occurring in the 6 days from April 10 to 15

The occurrence of the cases, by company, is shown in Figure 3 † It will be seen that the outbreak occurred in all companies at about the same time

Only 4 cases of a similar clinical disease are known to have occurred in the other battalions of the regiment These 4 men were all members of the 2nd Battalion and all had attended the showing of training film in the hay barn in the 3rd Battalion area on the night of March 25 This was the only time 3 of them had been in the area, but the other patient was a frequent visitor

The explosive character of the outbreak would point to some common source of infection applicable to the entire battalion Water is unlikely as a source of infection because the unit's water supply came from an engineer point which supplied other units which had no disease

It would seem that the infection occurred during the period the battalion was bivouacked near Pagliana, since this was the only time the entire unit was brought together Assuming it to have occurred in this area, the time interval between possible exposure and onset of the outbreak fits exactly the incubation period previously estimated, 14 to 26 days In speculating upon the possible sources of infection associated with the area, suspicion immediately centered around the barn where the motion pictures were shown, particularly when one considers the 3 cases in men from the 2nd Battalion who had visited this barn

* See Figure 51, an adaptation of the figures mentioned here

† I e, in Robbins, Gauld and Warner

INVESTIGATION OF AN EPIDEMIC *

In undertaking such an investigation, it is desirable to have an orderly procedure The following outline is suggested as applicable, in general, to such situations

A Preliminary analysis on the basis of the information available at the time the investigation is begun

1 *Verify the diagnosis* This may require only a brief review of the clinical findings, or may necessitate getting laboratory tests under way

2 *Verify that an epidemic exists*, by comparing the incidence of the disease with its usual incidence in the community

3 Orient the epidemic as to *time* by determining the chronological distribution of dates of onset (the epidemic curve)

4 Orient as to *place* by determining the geographical distribution of cases

5 Orient as to *persons* by determining age, sex, race, and when possible, other characteristics of the cases, determine attack rates according to these characteristics

6 On the basis of a rapid preliminary analysis of the selection of the disease as to time, place and persons, formulate tentative hypotheses to guide further investigations Attempt to classify the epidemic as to mode of transmission as follows·

transmission by a common vehicle	single exposure continued exposure
propagated by	person-to-person spread arthropod vector animal reservoir

B Further investigation and analysis.

7 Search for additional cases which may not have been recognized or reported.

8 Determine what additional information is necessary to answer any questions formulated and to test tentative hypotheses Plan and conduct a detailed epidemiological investigation of all the cases (or of a representative sample of cases), using a suitable epidemiological case card Arrange for any special investigations needed to establish collateral cir-

* Maxcy, K F., 1956, Preventive Medicine and Public Health, ed 8, pp 1301-1302, New York, Appleton

cumstances, using laboratory facilities, engineering and other *expert consultation*

9 Analyze detailed data derived from case investigation, comparing attack rates among various pertinent groupings Try to identify the group selected for attack and discover the common source or vehicle *to which they were* exposed, if any Assemble results of collateral investigations.

10 Test various hypotheses which have been suggested to ascertain which one is consistent with all the known facts. Base conclusions on all pertinent [illegible] *upon any* [illegible] by itself [illegible] all the kr[illegible] until the s[illegible] evidence is consistent with only one hypothesis Formulate conclusions as to the source, *mode* of transmission and all other features of the epidemic which require explanation

A report of the investigation of an epidemic may be organized along the lines of the outline given above In addition, it should usually include a discussion of factors leading to the occurrence *of the epidemic, an evaluation* of the measures employed for its control, and *recommendations* for the prevention of similar episodes in the future

PROPAGATED EPIDEMICS

When the span *of time* of an epidemic wave is much greater than the average incubation period of the particular disease in question, then it can be assumed *that (1) exposure to* dissemination by a common vehicle has been prolonged, or that (2) the *infection is being* propagated by *progressive host-to-host transfer (contact transmission)*, or that (3) there *is a combination of common-vehicle dissemination* with *secondary contact transmission*

Frequently, the term "epidemic" refers only to a peak in the oscillating incidence of a disease more or less constantly prevalent in *a community*. How great *the increase of in*cidence must be before it is regarded as epidemic is a matter of judgment and is influenced by psychologic attitudes The greater the fear of a disease, or the more unusual it is *in a community*, the *smaller the increase* needed to justify use of the descriptive term Many statistical devices have been suggested for making the definition more objective and precise (Bundesen and Hedrich, 1925; Rich and *Terry, 1946*), but no definition has yet received general sanction. Dependence is placed in *general* upon comparing the current incidence of each specific infectious disease with its incidence in the past in the same population group and at the same time of the year. This *expected number* or *norm* is commonly expressed as a 3-year or 5-year *median of reported cases* When current incidence exceeds this number in several successive time periods, the disease shows a tendency which, *if sustained and great enough*, soon or late merits a pronouncement of the presence of an epidemic

Each infectious disease has a *seasonal* variation which follows a more or less regular pattern, *reaching a maximum distribution about* the same time each calendar year, when conditions are most favorable to transmission Each is *subject also to an interannual variation* or secular trend which may be slight or show wide fluctuations Some diseases manifest a cycle or *periodicity*, epidemic years occurring at fairly regular intervals of 2 or 3 years, or perhaps 4 or 5 years or *longer (Com*mission on Acute Respiratory Diseases, 1946) Others are entirely unpredictable in their annual behavior

EPIDEMIC THEORY

The simplest of all infectious diseases is measles *Table 10 (Wilson and Burke 1942,* 1943) illustrates the manner in which its incidence varies in any large city. By *progressive host-to-host transfer* the virus population maintains itself more or less continuously If it dies out completely, before *long it is rein*troduced by the importation of a case in the infective stage However, there is a rhythmical *variation in incidence* correlated with the season of the year increasing to a maximum in the spring and decreasing to a *minimum in* the summer months. The time at which the maximum incidence is reached in each year varies *within fairly wide limits* In some years, the total incidence is relatively low, in others it rises to a level regarded as epidemic These epidemic years appear to recur at fairly regular intervals in the same locality.

A century ago the periodicity of measles epidemics was known and discussed (Hirsch, 1883). The causes were thought to be obscure and complex, *although* it was generally

Epidemics culminate in May, 1918, March, 1921, March 1923, January, 1926, April 1928, January, 1932, May, 1935 March, 1937, March(?), 1940 In this period of 262 months there are 9 major peaks, but we must not count both ends The average time between peaks is 33 ± 7.9 months, not 2 years For the mean we write 33 ± 2.8 months In Glasgow we estimate 40 months between peaks from 1888 to 1927, incl, based on Soper's data (*J Roy Statist Soc London*, 92, 34 61 [1929]) How many peaks one counts depends on the interpretation one gives to the qualifying adjective major and what allowance one makes for seasonal interruption of an epidemic

accepted that the accumulation of susceptibles was an important factor A more precise numerical approach to the explanation of periodicity of measles began with the contribution of Sir William Hamer (1906) Following his lead, a biometrician (Soper, 1929) in the course of an examination of possible methods of forecasting common contagious diseases "was led to adopt the simplest mathematical postulate that would describe on a first measure the generally accepted mechanism of epidemic measles, if the accumulation of susceptibles were really the prime factor, to compare the deduced results with the observed facts and then modify the primary hypothesis" Soper's work in turn stimulated to elaborate the statistical approach to epidemic theory. This has elucidated quantitatively the relationships of the principal factors involved, and contributed to a rational explanation of the epidemiologic behavior of measles

The fundamental facts with which one starts are simple The biologic attributes of the measles virus and the requirements for infective transmission from case to susceptible remain relatively constant The dynamics of the mass reaction are due to the flow of the virus through the human population Sus-

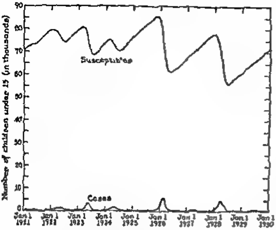

FIG 52 Secular trend of measles in Baltimore, Md, indicated by the estimated number of cases and susceptibles in the population under 15 years of age (Adapted from Fig. 3, Hedrich, A W., 1933, Monthly estimates of the child population "susceptible" to measles, 1900-1931 Am J Hyg. *17*, 626)

ceptibles effectively exposed to cases in turn become cases, cases recovering from the infection become immunes The susceptibles are being constantly recruited through birth and immigration, and depleted through becoming cases and immunes, or through deaths or emigration.

Upon the basis of a series of logical and reasonable approximations and assumptions, Hedrich (1933) made monthly estimates of the child population susceptible to measles in Baltimore from 1900 to 1931 As shown in Figure 52, during the 32-year period the calculated proportion of susceptibles in the population under age 15 did not rise above 53 per cent or fall below 32 per cent. The percentage figures are only approximations, but the implications are significant. When the proportion of susceptibles was low, the incidence of measles tended to be low, consequently, susceptibles accumulated When the proportion of accumulated susceptibles approached what McKendrick calls a *threshold density*, the situation was favorable for the support of an accelerated incidence of cases, or an epidemic. During a short period of time, the proportion of susceptibles fell rapidly as they became cases and subsequently immunes As the proportion of immunes increased, more and more cases failed by chance to make effective contact with susceptibles, and the incidence of new cases fell accordingly

It is apparent, therefore, that the principal factor determining the occurrence of propagated epidemics of measles is the proportion of susceptibles in the population at risk, and that the termination of an epidemic wave is due to the dampening effect of the cumulation of immunes and not necessarily to the complete exhaustion of susceptibles, since many escape effective exposure. The proportion of susceptibles required to support an epidemic, and per contra the postepidemic proportion remaining, will vary in every community, and even in the same community at different times of the year

By utilizing the simplified premises in measles, and representing the 4 principal factors by appropriate symbols, it is possible to derive a dynamic equation by which, given (1) the number of cases, (2) the number of susceptibles, (3) the number of the total population, and (4) assuming an arbitrary value for the *contact rates* in one time period of 14 days, the number of new cases which *will arise in the successive time* periods of the same length can be calculated In a community where sufficient data are available, the correspondence between cases predicated by such a formula and the cases observed is reasonably good within certain limits The same kind of reasoning and mathematical postulations can be applied to other infectious diseases However, the factors which go into the equation become more complex, and for an increasing proportion one is unable to obtain numerical values from observations made in nature The practical usefulness of the statistical approach to epidemic theory becomes correspondingly limited

EXPERIMENTAL EPIDEMIOLOGY

Another approach to the discovery of laws or general principles governing the behavior of infectious diseases in human populations is through observations made upon *epidemics in experimental animal colonies* Notable among the many contributions are those made by Theiler (1941) on mouse encephalomyelitis; by Traub (1939) upon choriomeningitis in mice; by Fenner (1948) upon mousepox (infectious ectromelia) of mice; by Webster

and his associates (1932, 1946) on salmonella, pasteurella, pneumococcus and Friedlander bacillus infections; by Topley and his associates (Greenwood, Hill, Topley and Wilson, 1936, Topley, 1942) on salmonella, pasteurella and ectromelia virus infections These studies are too extensive to permit detailed review.

The general procedure was to assemble uninfected animals in unit cages, the arrangement of which could be altered to simulate a community of any desired size. A constant regimen of cleaning and feeding was established, and appropriate measures taken to prevent the introduction of extraneous, pathogenic micro-organisms An epidemic was started by introducing into an uninfected animal colony a certain number of animals infected with the microparasite selected for the experiment The course of the subsequent epidemic was indicated by the occurrence of specific deaths, proved by necropsy and culture Effort was made to hold all of the important factors constant except the one under examination, and to note the effect this variable had upon the course of an artificially produced epidemic

It became evident very early in this work that a constant genetic stock of experimental animals was fundamental to control of the host variable As had long been known to the plant pathologists, it was found possible within certain limits by selective mating to breed out lines that were relatively resistant or relatively susceptible to infection with a particular micro-organism, such as *S enteriditis*, the cause of mouse typhoid It was demonstrated, for example, that there may be selected promptly from a hybrid stock of mice, of which 40 or 50 per cent die, lines in which as high as 95 per cent and as low as 15 per cent succumb following a standard dose of *S enteriditis* This afforded experimental evidence of the importance of innate differences in resistance genetically transmitted in human families, lines of descent, races, to a particular microparasite, a phenomenon well illustrated by the differences in the host reaction of the white and the Negro races to infection with *Myobacterium tuberculosis*

The possible importance of nutrition of the host to natural resistance to infection was appreciated If a diet were so poor in quality or quantity as to bring about a state of debility, experimental animals whose lives were already in jeopardy from the consequences of produced deficiency would have a higher death rate than well-nourished animals if subjected to the added insult of infection Obviously, it was desirable to hold this factor constant by providing a uniform and well-balanced diet It was noted, however, that a diet which was well balanced for normal growth and development was not necessarily well balanced in its effect upon host resistance to infection with a specific micro-organism This question has been explored extensively by many investigators in relation to various infections experimentally produced in animals It has been demonstrated that specific (natural) resistance can be influenced by nutrition when the stock is genetically heterogeneous and the pathogenic population to which it is exposed is heterogeneous in the sense that it contains an array of variation in terms of capacity to produce disease (Schneider, 1951). These studies have advanced the understanding of the underlying mechanisms implied in the terms resistance and susceptibility, but diet was of very limited importance as one of the variables affecting the results of experimental epidemics produced by *Salmonella enteriditis*

The variability in the biologic potentialities of the strains of infecting micro-organism employed received considerable attention A theory had been advanced by certain speculative epidemiologists that the rise and the fall of an epidemic, such as the pandemic of influenza, are due principally, if not wholly, to a progressive increase and decrease, respectively, in virulence of the specific agent, the increase being brought about by rapid passage of the infecting agent in human beings during the early part of an epidemic, and the decrease occurring because the infecting agent is subjected as an epidemic progresses to more resistance and less frequent passage as the result of increasing immunity in the host population To test this theory, methods were devised for measuring the virulence of a specific strain of micro-organism for groups of mice by administering a fixed dosage Sample cultures were obtained from animals dying at various times during artificially produced epi-

demics. Comparative titrations were made on strains from epidemics of pasteurellosis in rabbits, chickens and mice. Similar titrations of two serologic types were made during the course of mouse typhoid infections in mouse populations A total of 300 or 400 titrations were made under many conditions to test the theory of fluctuating virulence "The results were invariably negative and showed a constancy and fixity of disease-producing power of a given strain of organisms under all conditions of natural infection . . ."

From this experience, many were inclined to believe that in all instances changes in biologic potentialities of specific microparasitic species are of little or no importance in determining the rise and the fall of epidemic waves While this may be true within certain limits for many parasitic species, there are some which are more unstable and have considerable capacity for selective variation and adaptation in those qualities which determine its pathogenicity for a human population at a particular time and place. Reference is made here in particular to recent studies on the variability of viruses of influenza (Burnet, 1951) and of poliomyelitis (Sabin, 1951). The possibility that bacterial and viral dissociation may occasionally play a role cannot be ignored (Zinsser and Wilson, 1932). The development of sulfadiazine-resistant or penicillin-resistant strains of bacteria is a pertinent indication of what may happen in nature

In one series of studies it was demonstrated that, when infected animals were introduced in a closed universe of susceptible animals, the ensuing epidemic quickly subsided as susceptibles died or became immune, although some escaped infection An epidemic started in this manner could be maintained in an open universe if sufficient susceptible recruits were added at regular intervals If the conditions were held relatively constant, the balance between the microparasites and the host population tended to reach a stabilized equilibrium This was violently disturbed by a major change in the contact rate, which was accomplished by bringing a large number of animals previously dispersed in small single cages into a single colony in a large cage.

These and other experiments added support to some of the generalizations derived from experiences with epidemics in human populations under natural conditions They emphasized particularly the accelerating effect upon incidence of an inflow of susceptibles into an infected community, and of aggregation of individuals into large groups (crowding) and per contra the dampening effect upon incidence of accumulation of immunes. But the actual quantitative importance of each of these factors varies with the disease, its mode of transmission, the host relationships involved, and the local circumstances

EXTRAHUMAN RESERVOIRS

In the preceding paragraphs, for the sake of simplicity in discussing factors which determine incidence, attention was concentrated upon infections which are transmissible directly from one individual to another of the same host species. These are due to microparasites which in the process of host-wandering, mutation and selective adaptation have become so highly specialized in their nutritive requirements that they can grow and multiply only when enzyme systems of certain human tissues and cells are available to them. Other disease-producing agents are sufficiently plebeian in their nutritive requirements to be able to find conditions favorable for their propagation in selected organs and tissue cells not only of man but of other mammals, birds or arthropods.

Man, along with many other species of mammal, serves only as an aberrant host for the virus of rabies, which is dependent for its continuous propagation upon the canine species The virus of yellow fever can grow in the cells of many species of mammal, and in several species of mosquito found in the jungles of South America and Africa Primarily, the virus is native to jungle life, apparently principally dependent upon alternation of monkey and mosquito hosts Occasionally, it is transmitted to man, who, as an aberrant host, has "jungle" yellow fever, which is usually a sporadic disease But if an infected human being happens to reside in a community in which there are sufficient numbers of a domesticated species of mosquito, *Aedes aegypti*, and is bitten by them, they serve as efficient vectors in propagating an epidemic of yellow fever. Since the virus cannot make an effective exit from the human

host, except through the medium of blood-sucking mosquitoes, the disease is not otherwise transmissible directly from man to man

Rickettsiae are microparasites of arthropods. In the process of evolution they have become adapted to propagation in selected cells of man and other mammals. For example, *R tsutsugamushi*, the cause of scrub typhus, has established a symbiotic relationship with certain species of trombiculid mites (Blake, Maxcy, Sadusk, Kohls and Bell, 1945) Mites become infected in the larval stage, and rickettsial progeny are passed from generation to generation through the successive stages of development of the mite—nymph, adult, egg, larvae, etc This transovarial passage of the microparasite apparently does not interfere with normal growth, development and activity of the mite host Only in the larval stage does the mite seek a meal of tissue fluids from a mammal In the ecology of the mite vector, field rats are the most accessible source of such nutritive fluids In the process of feeding, the larval mite infects a rat, which suffers an inapparent infection While the rickettsiae are multiplying actively and being liberated into its peripheral circulation, the rat's tissue fluids are a medium of distribution to uninfected larval mites which happen to be feeding upon the animal at the time Thus the chain of transmission is maintained in nature without apparent detriment to either mite or rat population When an infected mite by chance feeds upon and infects a human being, the host reaction is manifested by the clinical signs, symptoms, and course of illness classified under medical terminology variously as tsutsugamushi disease, scrub typhus, mite typhus, etc Since larval mites have little or no opportunity to feed upon man during the stage of his illness when rickettsiae are in the peripheral circulation, and since the rickettsiae fail to make an effective exit from the human host in excretions or secretions, the infection is not passed directly from man to man

These illustrations serve to indicate the complexity of the factors which determine the incidence in human populations of diseases which are caused by microparasites with multiple host relationships The occurrence of human cases is the visible indication of the existence of an *extrahuman reservoir* There is some difference of opinion as to whether the term reservoir should be used to refer only to the principal mammalian or avian hosts or whether it should include arthropod hosts as well Rationally, it could be used with advantage to refer to the whole underlying extrahuman mechanism by which a specific microparasitic population is continuously maintained, including the specialized ecology necessary to support the biologic relationships involved

EVALUATION OF PREVENTIVE MEASURES

Knowledge of most of the common infectious diseases has advanced to a point where the principal factors which determine incidence and distribution are generally recognized However, with many, if not all, there is need for epidemiologic studies which will define more exactly these factors and establish their relative (crudely quantitative) importance. One may glibly state, for example, that measles is air-borne. However, it remains to be determined to what extent the virus is conveyed on particles, more or less indirectly by air currents from a case to susceptibles, the particle size which when inhaled will reach the mucous surfaces of the upper respiratory tract essential for infective contact, to what extent the virus is conveyed rather directly from person to person in what might be called conversational proximity, to what extent the virus is conveyed by contamination of articles with infective secretions and transferred by hands to the mouth of a susceptible, etc. The relative importance of these different routes of transmission must be evaluated if measures introduced to prevent spread are to be maximally effective To put the thought in more general terms, it is necessary to effectiveness that measures of prevention be directed against those conditions which are of actual importance in the particular situation rather than against the much wider range of conditions which may possibly contribute to the prevalence of a disease Innumerable instances could be cited in which public health campaigns or measures, thought to be theoretically sound and rationally conceived, failed to accomplish the reduction which was expected.

demics. Comparative titrations were made on strains from epidemics of pasteurellosis in rabbits, chickens and mice Similar titrations of two serologic types were made during the course of mouse typhoid infections in mouse populations A total of 300 or 400 titrations were made under many conditions to test the theory of fluctuating virulence "The results were invariably negative and showed a constancy and fixity of disease-producing power of a given strain of organisms under all conditions of natural infection . . "

From this experience, many were inclined to believe that in all instances changes in biologic potentialities of specific microparasitic species are of little or no importance in determining the rise and the fall of epidemic waves While this may be true within certain limits for many parasitic species, there are some which are more unstable and have considerable capacity for selective variation and adaptation in those qualities which determine its pathogenicity for a human population at a particular time and place Reference is made here in particular to recent studies on the variability of viruses of influenza (Burnet, 1951) and of poliomyelitis (Sabin, 1951). The possiblity that bacterial and viral dissociation may occasionally play a role cannot be ignored (Zinsser and Wilson, 1932). The development of sulfadiazine-resistant or penicillin-resistant strains of bacteria is a pertinent indication of what may happen in nature

In one series of studies it was demonstrated that, when infected animals were introduced in a closed universe of susceptible animals, the ensuing epidemic quickly subsided as susceptibles *died or became immune, although* some escaped infection. An epidemic started in this manner could be maintained in an open universe if sufficient susceptible recruits were added at regular intervals. If the conditions were held relatively constant, the balance between the microparasites and the host population tended to reach a stabilized equilibrium This was violently disturbed by a major change in the contact rate, which was accomplished by bringing a large number of animals previously dispersed in small single cages into a single colony in a large cage

These and other experiments added support to some of the generalizations derived from experiences with epidemics in human populations under natural conditions *They* emphasized particularly the accelerating effect upon incidence of an inflow of susceptibles into an infected community, and of aggregation of individuals into large groups (crowding) and per contra the dampening effect upon incidence of accumulation of immunes. But the actual quantitative importance of each of these factors varies with the disease, its mode of transmission, the host relationships involved, and the local circumstances.

EXTRAHUMAN RESERVOIRS

In the preceding paragraphs, for the sake of simplicity in discussing factors which determine incidence, attention was concentrated upon infections which are transmissible directly from one individual to another of the same host species. These are due to microparasites which in the process of host-wandering, mutation and selective adaptation have become so highly specialized in their nutritive requirements that they can grow and multiply only when enzyme systems of certain human tissues and cells are available to them Other disease-producing agents are sufficiently plebeian in their nutritive requirements to be able to find conditions favorable for their propagation in selected organs and tissue cells not only of man but of other mammals, birds or arthropods.

Man, along with many other species of mammal, serves only as an aberrant host for the virus of rabies, which is dependent for its continuous propagation upon the canine species The virus of yellow fever can grow in *the cells of many species of mammal*, and in several species of mosquito found in the jungles of South America and Africa *Primarily*, the virus is native to jungle life, apparently principally dependent upon alternation of monkey and mosquito hosts. Occasionally, it is transmitted to man, who, as an aberrant host, has "jungle" yellow fever, which is usually a sporadic disease But if an infected human being happens to reside in a community in which there are sufficient numbers of a domesticated species of mosquito, ***Aedes aegypti***, and is bitten by them, they serve as efficient vectors in propagating an epidemic of yellow fever. Since the virus cannot make an effective exit from the human

has led in many instances in the past to the exploitation of biologic products and chemical substances which was unwarranted, and at times actually detrimental It has become painfully evident that evaluation by "clinical impressions" is unreliable

The basic requirements of field trials (Cockburn, 1957) upon human beings are well known, but the actual conduct of such an experiment is fraught with practical difficulties Ideally, two groups of persons a test and a control group, are placed under observation They must be alike in all essential respects, particularly those which relate to their susceptibility at the beginning of the experiment and their exposure to natural infection throughout the period of observation The substance to be tested must be administered without discrimination, if possible, alternate individuals should receive a placebo It is highly desirable that neither the subjects themselves nor the investigator who is responsible for their subsequent follow-up and observation should know who has received the test material and who has not In this manner, errors due to unconscious human bias may be obviated Individuals of both groups must be examined with equal frequency, care, and for equal periods, which are sufficiently long to ensure an adequate test of the protection afforded The criteria used in clinical diagnosis must be clearly stated The resulting attack rates in the two groups must be sufficiently large to be statistically significant

This is a basic outline of the kinds of problem encountered There are always many perplexing circumstances and occurrences tending to disturb the results for which allowance must be made in some manner

Illustration of this type of epidemiologic studies designed to evaluate critically an immunization procedure is found in the final report of a large-scale field trial of poliomyelitis vaccine (Salk) designed to evaluate protection afforded against paralytic attack (Francis et al, 1957) This study was comprised of two parts, conducted at the same time under a single plan for the collection of data, the so-called *placebo plan*, designed to assure strict comparability between the vaccinated and the control subjects This was accomplished by randomly selecting the two groups from a single volunteering population and by concealing the specific nature of the inoculum which each person received until all data were assembled and a final diagnosis made The *observed control plan* involved the vaccination of an identified segment of the children, while others were openly designated as the comparison group, without placebo The two studies involved different people in different areas and with different degrees of exposure to poliomyelitis The data for investigation were acquired from 211 different areas in 44 states and some from Canada and Finland They represent the results obtained with multiple lots of vaccine of varied potency used in areas where the nature and the degree of challenge differed widely

Intensive effort was made to assure completeness of registration, accurate records of inoculation, conformity with procedures for reporting of cases no matter what the prevalence of the disease, detailed, objective investigation of cases and their diagnostic classification under criteria considered by expert advisors to be valid within limits of diagnostic accuracy The data are highly reliable and complete The official study period was defined 2 weeks after the third injections were completed in a given area, corresponding to the time when specimens of serum were obtained for the measurement of antibody response The time was specifically determined for each area, but generally was about the middle of June To December 31, 1954, of the 1,012 cases considered to be poliomyelitis reported to the Vaccine Evaluation Center, in the total population of 1,829,816,428, or 57 per 100,000, developed in placebo areas, and 584, or 54 per 100,000, occurred in observed study areas.

Burnet, F M, 1951, Some biological implications of

SECONDARY ATTACK RATE

A classic example of critical evaluation of measures to prevent the spread of common contagious diseases is afforded in the development and the use of the secondary attack rate, with particular reference to scarlet fever and diphtheria, by Dr Charles V Chapin, for many years health officer of Providence, R I It is related in some detail by Frost (1938) in a discussion of the familial aggregation of infectious diseases

The principles and the applications of the methods have the merit of yielding information which is easily understood and directly related to the practical problems of the health officer The ultimate epidemiologic unit in a civil community is the family or household, a group of people (Buck, 1956) mostly of close kinship, sharing a common environment, living in close contact in a manner easily described, and usually under the eye of a single medical or lay observer The degree of contagiousness of different diseases can be measured by a statistical index derived from familial experience The first case to occur is designated as a primary or index case A census is made of the exposed members of the family, classified by age, sex, or other conditions which it is desired to take into account, especially with regard to their past history of having had the disease in question or specific immunization against it Then a record is kept of cases occurring in any member of the household within time limits, with reference to the index case, set specifically for each disease, so as to include those probably infected by contact It is then possible to summarize the observations on a large number of families and obtain an index of average experience based upon the ratio between secondary cases and exposed persons, or exposed persons specified as to age, sex, relationship, previous history, immunity status, or other quality However, it is to be noted that this index is based upon the frequency of secondary clinical cases following the occurrence of the index clinical case It does not take into consideration the spread by subclinical infections It is useful nonetheless in answering certain questions· for example, (1) given a case of a communicable disease in the family, what is the risk of *clinical attack* borne by others in the same household within specified periods of time? (2) to what extent can risk of clinical attack be reduced by preventive measures, such as sending the index case to the hospital or immunization of exposed susceptibles? It is pertinent to remark in this connection that a practical objective of preventive medicine is to decrease the risk of disease and death but not subclinical, immunizing infections

EVALUATION OF IMMUNIZATION AND CHEMOPROPHYLAXIS

The evaluation of preventive measures in reducing the incidence of a disease in a large population unit, such as a city, is fraught with difficulty Allowance must be made for the natural trend of the disease due to changes in complex factors other than those which are effected by the administrative measures Occasionally, nature performs an experiment, which if brought under adequate epidemiologic perception, answers a crucial question A classic example, which should be read by every student of epidemiology, is presented in the observations made by John Snow (1865) on the relation of the purification of water supplies to the incidence of cholera in different districts of London during the epidemic of 1854-55

However, nature seldom sets the stage for a scientific experiment in such a manner that it is possible to observe two population groups alike in all important respects except one So it becomes necessary to set up such groups artificially if many questions as to the effectiveness of control measures are to be answered.

The same kind of considerations enter into epidemiologic investigations designed to evaluate the prevention of an infectious disease by immunization or by the prophylactic administration of antibiotics or chemical compounds The preliminary work in testing effectiveness and safety is carried out in the *laboratory upon experimental animals,* where a susceptible species is available. When sufficient evidence has been accumulated to justify the use, the final evaluation of the efficacy of such agents can be obtained *only by human trial* Furthermore, these observations must be so controlled as to merit scientific acceptance of results Failure to meet this necessity

Arthropod-Borne Animal Viruses

GENERAL CONSIDERATIONS

Arthropod-borne animal (arbor) viruses are defined as viruses which have the capacity to infect certain vertebrates—mammals and birds—and to multiply in the body of arthropods. Except under unusual circumstances, these viruses are not capable of spreading from vertebrate to vertebrate without the agency of an arthropod. The arthropod is the vector and becomes infected, generally, by ingesting blood from a vertebrate host at a time when the virus circulates in the latter. After a period of days, designated extrinsic incubation, the vector, by biting, can transmit the disease to a new susceptible host. Infection of the vector can also occur by transovarian transmission of the virus in the case of ticks. So far as is known, the virus does not cause any apparent ill effects on the vector, nor are any lesions detectable in the tissues of the arthropod.

It is the ecologic fact of the relationship between vertebrate and arthropod that brings together in a family all the viruses considered in this chapter; conclusive proof for support of the preceding definition is not at present available for all viruses concerned. In such cases, the virus is still included, either on the basis of serologic relationships with other agents belonging to the arbor family (for example, bat salivary gland virus), because the virus has been isolated from wild-caught arthropods (Anopheles A, Wyeomyia), or because it has been possible experimentally to infect arthropods and propagate the virus in them through several passages (Bwamba).

The explicit definition of an arbor virus, as multiplication in the arthropod without damage, excludes viruses which are transmitted mechanically by an arthropod, i.e., in the absence of multiplication in its body, and viruses which are intrinsic pathogens of arthropods. Finally, the term "animal" is included in the definition to distinguish these agents from viruses which are pathogens of plants and multiply in arthropods. The abbreviation arbor has been used because of its simplicity.

HISTORY

In the past 30 years nearly 50 distinct viruses have been found to be arthropod-borne, and continuing searches add new viruses to the group every year. Although they have been found on every continent, information on their geographic distribution is still fragmentary (American Geographical Society, 1952, 1954). The history of each virus, or of the diseases caused by them, is given in subsequent chapters. In this chapter the events are described that led to the establishment of the arbor family of viruses and its groups.

The crucial participation of arthropods, as vectors, in the dissemination of diseases caused by some viruses has been known for a long time. The first instance in which dependence

constitute a definite serologic group. At least 14 additional viruses were excluded because their role in human infection is unclear and they have not yet been fully described. This is mentioned to emphasize the increasing number of new arbor agents that are being isolated. Arthropod-borne viruses of strictly veterinary interest were also excluded.

Basis for Classification. The present classification is based on serologic cross-reactions between viruses (Casals, 1957). All cross-reacting agents have been placed in a group; no virus has been found, so far, to show relationships with more than one group. Sera produced by repeated injections of a virus into an animal generally have shown a broader range of overlap within the group than sera produced by a single injection. Three different tests, CF, HI and NT, have been used for the detection of cross-reactions; with the better-studied groups, A and B, the HI test has given a broader spectrum of cross-reactions than the CF test, and the intracerebral NT test has been the more specific. With Group C, on the other hand, the CF test seems to be more inclusive, but even here the HI test has brought together all the viruses studied in the group. The classification shown in Table 11 derives from the results of HI tests with hyperimmune sera. Some viruses, particularly those of the Russian hemorrhagic fevers, have been classified on the basis of CF tests. Viruses that have cross-reacted in CF and NT tests have always done so within the group as established by HI tests.

As shown in Table 11, there are 3 groups of arbor viruses recognized, A, B and C. A considerable number of viruses that have not shown cross-reactions with any of the groups are left ungrouped. Possibly, in the future some of the latter may be joined to one of the established groups, or, since by NT and CF test reproducible cross-reactions have been found between some of the ungrouped viruses (Whitman, 1956; Casals, 1957), new groups may be identified.

Within Groups A and B, there are viruses which are more closely allied among themselves than to other agents in the group; these subgroups or complexes can be demonstrated by means of the less inclusive tests, CF and NT, or by the HI test using sera derived from experimental animals given a single injection of virus. These subgroups or complexes are:

Group A: (1) Chikungunya, Mayaro, Semliki Forest. (2) Sindbis, WEE.

Group B: (1) Dengue types 1 and 2. (2) Ilheus, JBE, Murray Valley encephalitis (MVE), SLE, WN. (3) Diphasic meningoencephalitis, Kyasanur Forest disease (KFD), Louping-ill, Omsk hemorrhagic fever, RSSE. The last subgroup is composed of agents so closely related serologically that it is questionable whether they are different entities. (4) Uganda S, YF, and possibly Zika.

The above classification omits entirely all other biologic properties of the viruses, i.e., host range, virulence by different routes of inoculation, length of incubation, type of disease produced in man and vector or arthropod from which it has been isolated, some of which may be important in their characterization. These properties are important, and characterization of a virus may be speeded con- [illegible]

classification is that, at present, the immunologic properties of a virus appear to lend themselves most readily to study and to be the most reproducible and stable from strain to strain.

Implications of Grouping. The existence of groups and the serologic overlaps on which they are based are considered as being due to antigenic constituents common to the related viruses. The associations in groups are of more than taxonomic significance; they are of importance in diagnosis and in cross-immunity (Casals, 1957). After inoculation of a virus into a fresh experimental animal, serum antibodies appear against the inoculated virus and against other viruses of the same group; the presence and the titer of the heterologous antibodies depend on the time between inoculation and bleeding, and on the virus inoculated. Inoculation of a virus into an animal previously injected with another virus from the same group provokes a general antibody response against all viruses of the group, which in breadth of overlap and in titer is far greater than the sum of the responses that each virus would elicit separately. In other words, a synergistic effect is demonstrable.

on a vector for the transmission of a virus infection of man was proved is yellow fever (YF) In early reports of the Yellow Fever Commission, Reed, Carroll and Agramonte (1901) gave conclusive proof that an arthropod vector, a mosquito, was essential for the natural cycle of the disease as it infects man. Doerr, Franz and Taussig (1909) investigated outbreaks of phlebotomus or sandfly fever and proved not only the filterability of the etiologic agent but also the fact that an arthropod vector was involved, in this case, a midge (Phlebotomus) Similarly, with another widespread disease, dengue, studies on its epidemiology conducted between 1906 and 1931 (see Chap 16), showed that in this disease too an arthropod vector, a mosquito, was involved Still another type of arthropod vector, a tick, was described by Gordon et al (1932) in connection with louping-ill; and, as reported by Silber and Soloviev (1946), a tick is also considered the vector of Russian spring-summer encephalitis (RSSE) In this disease, ticks are not only the vector, but they may well be a natural reservoir, as there seems to be evidence of transovarian transmission of the virus Finally, with more recent developments, emerged the recognition of the vector role played by arthropods, i e, mosquitoes, in the transmission of certain viruses which show neurotropic tendencies in clinical infections of man These diseases, e g, western equine encephalitis (WEE), St Louis (SLE) and Japanese B (JBE) encephalitis, were designated by Hammon and Reeves (1945) arthropod-borne viral encephalitides

In addition to the detection of ecologic or epidemiologic similarities, it has become recognized that many of the viruses in the arbor family fall into groups, the members of which are more or less closely related to each other and sharply separable from viruses belonging in other groups; this grouping has been made on the basis of antigen-antibody relationships detected by immunologic reactions

Interest in immunologic relationships began in the late 1930's, shortly after new agents, then designated "neurotropic," were discovered There are numerous reports in the literature that suspected serologic relationships between viruses could not be demonstrated, while subsequent work has shown them to exist. Advances in methods of study are in great part responsible for the detection of antigenic relationships Definite cross-reactions among 3 neurotropic viruses were detected by Smithburn (1942), who found by means of the neutralization (NT) test that West Nile (WN) virus and those of SLE and JBE were related Casals and Webster (1943, 1944) showed that the viruses of RSSE and of louping-ill were, by complement-fixation (CF) and NT test, closely related, if not identical Havens et al (1943) detected cross-reactions by CF test between eastern equine encephalomyelitis (EEE) and WEE viruses. The extensive use of the CF test for the investigation of cross-reactions has been of great value With this test, Casals (1944) confirmed the existence of common antigens among SLE, JBE and WN viruses, Hughes and Perlowagora (1950) found an overlap between SLE and Ilheus Additional cross-relationships were found by Sabin (1950), who was able to show, by CF test, that certain neurotropic viruses, JBE and WN and some non-neurotropic agents, dengue type 1, dengue type 2 and YF, were related Sweet et al (1953) reported cross-reactions by hemagglutination-inhibition (HI) test between SLE and dengue viruses In discussing these findings, Hammon (1948) and Theiler (1951) drew attention to the close similarity that a number of arbor viruses show in their epidemiologic patterns and ecology and the need for a general rather than an individual study of these agents. In a systematic study of a number of these viruses, using the hemagglutination (HA) and HI tests, Casals and Brown (1954) demonstrated extensive and sharply defined serologic relationships which permitted a number of arbor viruses to be assembled in two well-defined groups, designated A and B. Casals (1957), in extending this work, reported the existence of an additional group, C, and that there could be detected in Groups A and B subgroups, or complexes, of viruses closer among themselves than to the remaining agents of the group

CLASSIFICATION

In Table 11 are listed all the arbor viruses described in the literature A few soon to be described are included because there is evidence that they infect man or because they

constitute a definite serologic group. At least 14 additional viruses were excluded because their role in human infection is unclear and they have not yet been fully described. This is mentioned to emphasize the increasing number of new arbor agents that are being isolated. Arthropod-borne viruses of strictly veterinary interest were also excluded.

Basis for Classification. The present classification is based on serologic cross-reactions between viruses (Casals, 1957). All cross-reacting agents have been placed in a group; no virus has been found, so far, to show relationships with more than one group. Sera produced by repeated injections of a virus into an animal generally have shown a broader range of overlap within the group than sera produced by a single injection. Three different tests, CF, HI and NT, have been used for the detection of cross-reactions; with the better-studied groups, A and B, the HI test has given a broader spectrum of cross-reactions than the CF test, and the intracerebral NT test has been the more specific. With Group C, on the other hand, the CF test seems to be more inclusive, but even here the HI test has brought together all the viruses studied in the group. The classification shown in Table 11 derives from the results of HI tests with hyperimmune sera. Some viruses, particularly those of the Russian hemorrhagic fevers, have been classified on the basis of CF tests. Viruses that have cross-reacted in CF and NT tests have always done so within the group as established by HI tests.

As shown in Table 11, there are 3 groups of arbor viruses recognized, A, B and C. A considerable number of viruses that have not shown cross-reactions with any of the groups are left ungrouped. Possibly, in the future some of the latter may be joined to one of the established groups, or, since by NT and CF test reproducible cross-reactions have been found between some of the ungrouped viruses (Whitman, 1956; Casals, 1957), new groups may be identified.

Within Groups A and B, there are viruses which are more closely allied among themselves than to other agents in the group; these subgroups or complexes can be demonstrated by means of the less inclusive tests, CF and NT, or by the HI test using sera derived from experimental animals given a single injection of virus. These subgroups or complexes are:

Group A: (1) Chikungunya, Mayaro, Semliki Forest. (2) Sindbis, WEE.

Group B: (1) Dengue types 1 and 2. (2) Ilheus, JBE, Murray Valley encephalitis (MVE), SLE, WN. (3) Diphasic meningoencephalitis, Kyasanur Forest disease (KFD), Louping-ill, Omsk hemorrhagic fever, RSSE. The last subgroup is composed of agents so closely related serologically that it is questionable whether they are different entities. (4) Uganda S, YF, and possibly Zika.

The above classification omits entirely all other biologic properties of the viruses, i.e., host range, virulence by different routes of inoculation, length of incubation, type of disease produced in man and vector or arthropod from which it has been isolated, some of which may be important in their characterization. These properties are important, and characterization of a virus may be speeded considerably by preliminary investigation of some of its biologic properties other than serologic. The basic principle in proposing the above classification is that, at present, the immunologic properties of a virus appear to lend themselves most readily to study and to be the most reproducible and stable from strain to strain.

Implications of Grouping. The existence of groups and the serologic overlaps on which they are based are considered as being due to antigenic constituents common to the related viruses. The associations in groups are of more than taxonomic significance; they are of importance in diagnosis and in cross-immunity (Casals, 1957). After inoculation of a virus into a fresh experimental animal, serum antibodies appear against the inoculated virus and against other viruses of the same group; the presence and the titer of the heterologous antibodies depend on the time between inoculation and bleeding, and on the virus inoculated. Inoculation of a virus into an animal previously injected with another virus from the same group provokes a general antibody response against all viruses of the group, which in breadth of overlap and in titer is far greater than the sum of the responses that each virus would elicit separately. In other words, a synergistic effect is demonstrable.

That a synergistic effect also occurs in man can be deduced from studies following natural infections or experimental inoculations. Injection of dengue type 2 virus in persons previously vaccinated with YF (Schlesinger et al, 1956), injection of JBE virus vaccine in children convalescing from infection with SLE virus (Hammon et al, 1956); and inoculation of 17D yellow fever vaccine followed by WN virus (Price, 1957), resulted in marked serologic responses to the viruses inoculated and to others of the same group, B After natural infection with JBE, SLE or YF viruses (Casals, 1957), two types of serologic response were noted In persons with no serologically demonstrable previous contact with a Group B virus, infection was followed by a response in the convalescent serum specifically against the infecting virus by CF and NT, and nearly specific by HI; in persons with demonstrable previous contact with a Group B virus, infection was followed by a general antibody response to the group

Additional evidence of synergism in Group B was brought out in the course of serologic surveys (Theiler and Casals, 1957) Essentially, two types of response were manifested in the degree of specificity within the group and in the height of the titers, in one type, the serologic response was either specific or relatively specific in the HI test, nearly always completely specific in the CF, and even more so in the NT test, this was interpreted as pointing to infection with only one agent Another type of response was characterized by a broad serologic response at high titers to all Group B viruses in either HI or CF tests, even in the NT test cross-protection was evident. This was interpreted as pointing to superinfection.

The serologic overlap within a group plus the synergistic effect raise several important questions about diagnosis, immunization and epidemiology Serologic diagnosis of a natural infection in man is complicated by the cross-reactions. When confronted with a positive test, one must ascertain whether the result is due to homologous or heterologous antibodies (Sabin, 1950; Casals, 1957).

On challenge of immunized animals, relationships are found between representatives of this family of viruses Such crossings have been mainly between the more closely allied members of a group, particularly when the challenge was given by peripheral inoculation Thus, cross-protections occur between RSSE and louping-ill viruses (Casals, 1944); between JBE and MVE viruses (Pond et al, 1955), between WN, MVE, SLE and JBE viruses (Hammon and Sather, 1956); and in Group A, between Semliki Forest and Chikungunya viruses (Casals, 1957). Work with human volunteers showed cross-protection between dengue types 1 and 2 (Sabin, 1950, 1952) These observations, when added to the more general and inclusive concept of grouping, particularly in view of synergism, have suggested the possibility of protection against many viruses of one group through vaccination with only 2 or 3 viruses of that group (Schlesinger et al, 1956, Hammon et al, 1956; Price, 1957)

In connection with immunity against all viruses of a group, the following observations may be significant Monkeys or mice immune to Uganda S virus, when challenged with YF virus, showed a moderate resistance to the challenge (Macnamara, 1953). After injection of WN virus into chicks immune to JBE virus, the viremia was at a lower level than in nonimmune birds, mosquitoes feeding on birds inoculated with WN virus alone become infected and can transmit infection more readily than mosquitoes feeding on WN-inoculated birds previously immunized against JBE virus (Price, 1956) WN virus had a similar effect on the susceptibility of monkeys to JBE virus infection (Imam and Hammon, 1957) Of particular interest is the observation by Theiler (Chap 15) that sera from persons with neutralizing antibodies against one of several Group B viruses—dengue types 1 and 2, Ilheus, WN—protected mice against YF virus in a peripheral NT test; the same sera failed to protect mice in the standard intracerebral NT test. The implication is that infection with a Group B virus other than YF had altered the host-immune status, with the result that under certain conditions his serum could neutralize the YF virus. All these observations raise the possibility of changed epidemiologic patterns in a human population previously exposed to a virus when a second virus of the same group is introduced. However, it cannot be ignored that viruses of a single group are known to coexist in the

same area, and clinical cases have occurred in persons who already had antibodies to another virus in the group

GENERAL CLINICAL PICTURE

Man can react to an arbor virus in different ways In their mildest form, human infections result in sufficient multiplication of the agent to bring about formation of antibodies but no clinical manifestations, i.e., inapparent infection In somewhat more severe infection, a virus may produce a mild generalized illness and antibodies without evidence of localization, i.e., atypical or aberrant infection. In severe infection, the virus may cause characteristic syndromes, i.e., typical or fully developed disease A well-defined syndrome is probably the least common manifestation of infection, because antibodies are so often found in the serum of persons who have not had such a syndrome In certain endemic areas varying proportions of normal persons with no history of encephalitis have antibodies to EEE, Venezuelan equine encephalomyelitis (VEE), WEE, JBE, MVE or SLE viruses (cf Casals, 1958, Chaps 13 and 14)

The fully developed diseases that these viruses cause are varied Details of the clinical disease are given in the following chapters, and only the more salient general characteristics are listed in Table 11 It is worthy of mention here that with many arbor viruses human infection presents a diphasic course The symptom complexes do not necessarily follow the serologic groupings A number of the agents have caused no known disease in man, and the only indication of human infection is the presence of antibodies In the case of a few viruses, antibodies have not yet been found.

GENERAL PROPERTIES

The description of the properties of these viruses frequently refers to characteristics of a laboratory strain, and such properties as host range, pathogenicity for a given animal by different routes of inoculation, and capacity to produce an HA antigen may have changed Other properties, such as resistance to the action of physical or chemical agents and stability of virulence, may be affected by the concentration of virus in the preparation, by its purity or by substances in the medium that protect the virus.

Of all the easily measurable properties, those depending on antigenic constitution manifested in serologic reactions seem to be the most stable, even when other biologic properties are changed, as in the YF strains, Asibi and 17D, the serologic reactions remain unaltered. Since serologic reactions are specific for each virus, at least within quantitative limits, serologic reactions can be used for final identification of these agents

Physical and Chemical Properties. The reported sizes of these agents place them generally in the range of 15 to 40 millimicrons There are a few exceptions. Anopheles A and B, Bunyamwera, Bwamba, Ntaya and Wyeomyia have a particle size in the range from 70 to 122 millimicrons (Smithburn and Bugher, 1953)

In aqueous tissue emulsions these viruses are unstable at room temperature In the frozen state at temperatures such as -20° C all but a few of the viruses are more stable, but the titer drops progressively, and in several months to a few years virus infectivity may be lost In a solid carbon dioxide cabinet in a container sealed to exclude CO_2, the viruses are very stable, the titer remains virtually unchanged for years. There are exceptions with some viruses, usually linked with the nature of the diluent and the pH of the preparation

Lyophilization is a good method of preservation, although there may be an initial decrease in titer with some The protective action of normal serum and serum derivatives such as bovine plasma albumin is generally observed Advantage is taken of this property for preserving the viruses and for maintaining the titer of virus dilutions during animal inoculations

The pH of the suspension is important in maintaining the titer and the stability of virus dilutions during animal inoculation A pH in the alkaline range is preferred for most viruses, usually between 7 and 8 The pH influence on viral preparations is particularly noticeable in HA, where pH 9 is nearly indispensable to the preservation of the agglutinating property.

In most studies, the viruses have been

easily inactivated by the action of formaldehyde or ether, even in low concentration, this distinguishes them from others such as the poliomyelitis and the encephalomyocarditis Most of the agents are easily inactivated by exposure to ultraviolet light or by heating at 60° C. for 10 to 30 minutes.

An important property of the viruses is their behavior when acted on by sodium desoxycholate *Agents studied have been inactivated* completely by concentrations that do not affect the following poliomyelitis, Coxsackie, encephalomyocarditis and mouse encephalomyelitis (Theiler, 1957) The property is defined so sharply that it has been advocated for differentiation of this family However, susceptibility to the action of sodium desoxycholate is not an exclusive property of these viruses, it is also characteristic of agents of the influenza family and lymphocytic choriomeningitis, but it can be considered an excluding property in that no arbor virus has been shown to be resistant to this chemical. Another way in which arbor viruses *can be differentiated from intestinal viruses* is in their behavior toward ion-exchange resins. The conditions under which arbor viruses are adsorbed to the resin, Amberlite IRC-50, differ markedly from those required for adsorption of such viruses as poliomyelitis, Coxsackie, encephalomyocarditis and mouse encephalomyelitis (Clarke, D H, 1957, personal communication)

Biologic Properties. Host range in nature and pathogenicity for laboratory animals are of great importance Variability among strains has become particularly apparent in relation to susceptibility of laboratory animals; hence, most of the biologic properties described with respect to host range and pathogenicity refer to standard laboratory strains

Information on host range in nature depends on *many factors. For obvious reasons,* some viruses, such as YF and the encephalitides, have been investigated more extensively than others, and more ■ known about them Some *viruses, such as WEE are easily established* in common laboratory animals, while others, such as dengue types 1 and 2, are not; WEE has been recovered often in nature and in many species, while *the other two, even* though known to be widely disseminated, have been isolated infrequently. Finally, the time during which a virus may be isolated depends on its infective titer in tissues and the length of time it persists. Most attempts at isolation in man are confined to blood tests; therefore, if the *period of viremia is not long* or if it precedes symptoms, circulating virus can be missed These considerations make it understandable that the present knowledge of natural host range and distribution is incomplete There are viruses, i.e , dengue types 1 and 2 and sandfly fever, Sicilian and Naples strains, that have been isolated only from man, another agent, WEE, has been isolated from man, horse, squirrel, deer, birds, pig, mosquitoes, mites and a kissing bug Yet, the evidence of antibodies in man throughout the world indicates that the distribution of dengue encompasses the tropical zone, whereas WEE ■ far more limited in distribution

The *experimental host range* varies widely Some information on the susceptibility of laboratory animals is helpful in identifying certain of the agents Newborn mice have become a *standard test animal because they* are generally most susceptible; isolations from nature can be made in newborn mice which will fail in adults Further, the use of the newborn mouse for the preparation of *HA* and CF antigens has greatly improved the quality of these reagents

The newborn mouse is apparently the most universally susceptible experimental host. *All* agents listed in Table 11 are pathogenic for newborn mice on intracerebral inoculation, although all strains as they occur in nature may not necessarily be so. The pathogenicity of the viruses for newborn mice by peripheral inoculation or for adult mice by intracerebral or *peripheral inoculation has been inconstant;* strains have been adapted and propagated in adult mice which were not pathogenic for them at first.

The *developing chick embryo* is a valuable experimental host; some viruses have been originally isolated more easily in chick embryos than in newborn mice. However, it is *not as generally susceptible as the newborn* mouse

Propagation in tissue culture is another means of study. Many agents have been *propagated in Maitland type minced tissue* culture. With the success achieved by the

use of cell suspension cultures with poliomyelitis virus, many laboratories are investigating the application of these newer methods When suitable cell types are used, the viruses tested grow and multiply in tissue culture with variable degree of cytopathogenic effect (cf. Chaps 13 to 19).

In identification of newly isolated strains of established viruses, the determination of their pathogenicity for a few common laboratory animals can be of considerable help In such studies, by observing the pathogenicity for newborn and adult mice, chick embryos and 1-day-old chicks and the survival time after inoculation, good presumptive evidence may be obtained for identifying the strain (Whitman, 1956), but this must be confirmed by serologic study

Antigenic Properties The viruses yield CF and HA antigens that react in vitro Using as source material the infected brain tissue from newborn mice and a variety of procedures of extraction, CF antigens may be prepared for all tested viruses in the family except Group C In early passages of Group C, the brain tissue yields generally a poor antigen, but the liver tissue from infected newborn mice yields high titer CF antigens HA antigens have been prepared from either brain tissue or serum from infected newborn mice with all viruses in Groups A, B (no information on louping-ill or Russian hemorrhagic fevers) and C and also from ungrouped viruses, Bunyamwera, sandfly fever, Naples and Sicilian strains, and Rift Valley fever However, not all strains of a given virus have produced an HA antigen, in Group C, some agents not listed in Table 11 have failed entirely

DIAGNOSTIC METHODS

The details of serologic diagnosis are presented in Chapter 10 however, the problems encountered with arbor viruses will be reviewed in general Essentially, diagnosis consists of identifying the virus or the specific antibody The existence of group relationships makes it necessary to determine not only that a given virus or its antigens react with a given antibody but also that the reaction is homologous, not heterologous

To identify the virus, the first step is to prepare an immune serum against the agent and, at the same time, to prepare and test an antigen for its capacity to hemagglutinate erythrocytes. If the antigen is active, a test against known positive sera will determine promptly the group to which the virus belongs or its absence of group connection Often, this test alone will give a definite lead to the identity of the virus, unless one is dealing with a new agent If the preparation fails to agglutinate red cells, the group and even the closer relations within the group can be determined by testing the antigen by CF against a collection of stock positive sera Whether or not the group is determined at this stage, final identification requires testing with homologous immune serum When this is available, CF, HI and NT tests are carried out in which the isolate is set up against several known sera, and the serum for the isolate against several known viruses or their antigens In this manner, the homologous and the heterologous reactions determine whether the isolate is identical with a known agent. Occasionally, it is difficult to decide whether one is dealing with a new virus, closely related to another already known, or with a slightly different strain of a known virus As this situation has arisen repeatedly in recent years with JBE, MVE, RSSE, louping-ill and some of the Russian hemorrhagic fevers, to mention only a few, a type species could be conceived as a cluster of different varieties grouped around a prototype, rather than as strains identical with a prototype. Where one cluster ends and the next begins is not always clear A method which gives promise of providing a rapid and accurate way of surmounting some of the difficulties in identification of certain Group B viruses has been explored This consists in the use of standard antisera which have been adsorbed with a heterologous but related virus in order to remove all except the specific homologous antibodies, then an HA antigen derived from the virus under investigation can be characterized exactly by the identity of the specific serum that inhibits it (Clarke, D H, 1957, personal communication)

Regarding detection of antibodies, it is accepted that CF antibodies do not persist long after clinical infection, and little is known of their presence and persistence after sub-

easily inactivated by the action of formaldehyde or ether, even in low concentration; this distinguishes them from others such as the poliomyelitis and the encephalomyocarditis. Most of the agents are easily inactivated by exposure to ultraviolet light or by heating at 60° C for 10 to 30 minutes

An important property of the viruses is their behavior when acted on by sodium desoxycholate. Agents studied have been inactivated completely by concentrations that do not affect the following poliomyelitis, Coxsackie, encephalomyocarditis and mouse encephalomyelitis (Theiler, 1957). The property is defined so sharply that it has been advocated for differentiation of this family. However, susceptibility to the action of sodium desoxycholate is not an exclusive property of these viruses, it is also characteristic of agents of the influenza family and lymphocytic choriomeningitis, but it can be considered an excluding property in that no arbor virus has been shown to be resistant to this chemical Another way in which arbor viruses can be differentiated from intestinal viruses is in their behavior toward ion-exchange resins The conditions under which arbor viruses are adsorbed to the resin, Amberlite IRC-50, differ markedly from those required for adsorption of such viruses as poliomyelitis, Coxsackie, encephalomyocarditis and mouse encephalomyelitis (Clarke, D H, 1957, personal communication)

Biologic Properties. Host range in nature and pathogenicity for laboratory animals are of great importance. Variability among strains has become particularly apparent in relation to susceptibility of laboratory animals, hence, most of the biologic properties described with respect to host range and pathogenicity refer to standard laboratory strains

Information on host range in nature depends on many factors For obvious reasons, some viruses, such as YF and the encephalitides, have been investigated more extensively than others, and more is known about them Some viruses, such as WEE are easily established in common laboratory animals, while others, such as dengue types 1 and 2, are not; WEE has been recovered often in nature and in many species, while the other two, even though known to be widely disseminated, have been isolated infrequently. Finally, the time during which a virus may be isolated depends on its infective titer in tissues and the length of time it persists. Most attempts at isolation in man are confined to blood tests; therefore, if the period of viremia is not long or if it precedes symptoms, circulating virus can be missed These considerations make it understandable that the present knowledge of natural host range and distribution is incomplete There are viruses, i e., dengue types 1 and 2 and sandfly fever, Sicilian and Naples strains, that have been isolated only from man; another agent, WEE, has been isolated from man, horse, squirrel, deer, birds, pig, mosquitoes, mites and a kissing bug. Yet, the evidence of antibodies in man throughout the world indicates that the distribution of dengue encompasses the tropical zone, whereas WEE is far more limited in distribution

The experimental host range varies widely Some information on the susceptibility of laboratory animals is helpful in identifying certain of the agents Newborn mice have become a standard test animal because they are generally most susceptible; isolations from nature can be made in newborn mice which will fail in adults Further, the use of the newborn mouse for the preparation of HA and CF antigens has greatly improved the quality of these reagents

The newborn mouse is apparently the most universally susceptible experimental host All agents listed in Table 11 are pathogenic for newborn mice on intracerebral inoculation, although all strains as they occur in nature may not necessarily be so The pathogenicity of the viruses for newborn mice by peripheral inoculation or for adult mice by intracerebral or peripheral inoculation has been inconstant, strains have been adapted and propagated in adult mice which were not pathogenic for them at first

The developing chick embryo is a valuable experimental host, some viruses have been originally isolated more easily in chick embryos than in newborn mice However, it is not as generally susceptible as the newborn mouse.

Propagation in tissue culture is another means of study. Many agents have been propagated in Maitland type minced tissue culture. With the success achieved by the

clinical intense viremia may be the most important sources of virus for vectors. A significant recent epidemiologic concept is that visibly healthy avian and mammalian hosts harbor the viruses and effectively provide them to vectors (Hammon, 1948, Theiler, 1951, Eklund, 1954).

The range of vertebrate species which may contract clinical infection or circulate virus in the blood stream is not known for every virus. Such information depends either on the experimental exposure and study of vertebrate hosts or on the detection of viremia under natural conditions.

Host-Vector Association. One or more arthropod species that can harbor and transmit the virus must associate closely with and prefer the blood of a vertebrate host receptive to the virus. The association must be close because the viremia is transient, and the vector is relatively short-lived. Each species of blood-sucking arthropod has an affinity for a vertebrate species or group of species. Detailed knowledge of vector-host preferences or dependencies is essential to the epidemiology of an arthropod-borne virus (Bates, 1949, Reeves, 1958). If the virus is to survive, the vector must have contact both with hosts in which viremia is pronounced and with susceptible hosts, in order to maintain the infection at epidemic or endemic levels. Earlier studies emphasized the relationship of suspected vectors to diseased human or animal hosts. This is an essential component of the epidemiologic pattern, but it may be more important to know how frequently vectors feed on vertebrate species having viremia without clinical symptoms. Even in studies of such classic infections as YF (Whitman, 1951), dengue (Smith, 1956) and the encephalitides (Ferguson, 1954), knowledge of host preferences or dependencies of primary vectors is limited. Detailed data on host preference from precipitin tests, bird malaria field epidemiologic studies and bait-trap studies illustrate the preference of primary vectors such as *Culex tarsalis* and *Culex univittatus* for the avian hosts of WEE, SLE and WN viruses (Reeves et al., 1944, 1954, Taylor et al., 1956, Dow et al., 1957).

In the laboratory many species of arthropods are effective vectors of the more extensively studied viruses, yet search for natural infection in endemic areas has failed to confirm their importance as vectors. Similarly, in many species of experimentally infected vertebrate hosts the virus may circulate in the blood, or the animal may be manifestly ill, yet evidence of their natural infection cannot be found, although they reside in endemic areas. Probably these efficient laboratory vectors do not usually feed on vertebrate hosts capable of biologic maintenance of the virus, and the effective hosts are not the blood source for efficient vectors in the field.

Under natural conditions the vector does not necessarily limit its blood feeding to the effective host. Characteristically, it will also feed on and transmit infection incidentally to species incapable of perpetuating the infection. Similarly, an effective vertebrate host will be bitten by other arthropod species incapable of perpetuating the infection.

Climate. Transmission depends on a climate favorable to completion of extrinsic incubation in the vector. Factors such as temperature, humidity and rainfall markedly influence the survival of the virus and the arthropod. The principal influences are on extrinsic incubation of the viruses, on the feeding activity or reproduction of the poikilothermic vector populations (Bates, 1949) and on the effect of physical environment on host populations.

If the vector is to transmit, during extrinsic incubation virus must pass from the lumen of the arthropod's intestinal tract to intracellular sites, multiply and reach the salivary glands in adequate quantity for an infectious dose to be inoculated by bite. The duration of the extrinsic incubation period is related inversely to temperature, being shortened by increased temperature. This undoubtedly reflects the effect of temperature on the metabolism of the poikilothermic vector and possibly on the virus. Epidemiologically, temperature is critical. When it is low the incubation is prolonged, and the cycles of transmission turn slowly. In temperate areas the arthropod-borne viruses are sometimes classified as spring-summer (RSSE), summer (WEE and SLE) or autumn-fall (JBE) infections. In part this marked seasonal limitation of clinical infections is dictated by the temperature requirements for extrinsic incubation. In contrast, in tropical areas temperatures may be

clinical attacks Hence, the CF test is not suited to surveys, but it is useful in diagnosis after clinical disease If compared with the NT test in surveys, the CF test probably would reflect the minimum rate of recent infection or perhaps a seasonal minimum infection rate In the CF, HI and NT tests, it is advisable to test each serum against several antigens or viruses. From a comparison of the respective titers of the serum against the different agents, a decision can be reached in most instances However, if a double or multiple infection with related viruses has occurred, interpretation may be difficult or impossible Neutralizing antibodies after clinical infection remain detectable for long periods, perhaps for life The duration of NT antibodies following subclinical infection is less well known The duration of HI antibodies has not been studied adequately, but apparently they persist considerably longer than CF antibodies Although the HI test is less specific in some groups than the NT test, the former is valuable in serologic surveys, particularly as a screening test for Group B antibodies in moderately to heavily infected endemic areas If the HI test alone does not answer the question of specificity, at least it selects positive and negative sera with considerable agreement with the results of NT tests The HI test separates positive sera from negative, while specificity is better shown by NT test.

EPIDEMIOLOGY

To understand the epidemiology of this family of viruses one must know their natural history in extrahuman hosts, because human infection generally is incidental to virus perpetuation. Studying the pattern of disease in human populations frequently assumes a position secondary to identifying the biologic circumstances on which the parasite depends for survival In the case of these viruses the usual epidemiologic approach is reversed· they are being recovered from arthropods before any accompanying infection or disease is identified in vertebrate hosts. Formerly, descriptive analysis of manifest infections led to identification of a virus and an arthropod vector

Transmission of virus from one vertebrate host to another depends on one or more arthropod species and will occur rarely, if at all, by other means such as contact between hosts. This dependence is proved or strongly implied by fairly constant association of the vector with the clinically or subclinically infected host and the absence of infection in the absence of the vector. Further, the virus can be isolated from a naturally infected vector species, as has WEE virus from *Culex tarsalis* or YF virus from *Haemagogus spegazzini*, and members of the species prove to be capable of transmitting the agent by biting an experimental host.

To learn whether all the necessary relationships exist between a host, a viral agent and an arthropod is a demanding task. In fact, the information is incomplete for most viral agents classified as arthropod-borne. Of the many types of blood-sucking insects and arachnids only 3 families, Culicidae, Psychodidae and Ixodidae, are clearly implicated as important biologic vectors of pathogenic viruses affecting man (Day and Bennetts, 1954, Reeves, 1958). The subsequent chapters present evidence that species such as *Culex tarsalis* for WEE, *Culex tarsalis* and *Culex pipiens-quinquefasciatus* for SLE, *Culex tritaeniorhynchus* for JBE, *Aedes aegypti*, *Aedes africanus* and *Haemagogus* sp for YF, and others are proved primary vectors

Biologic transmission consists of the following steps

1. A critical minimum amount of virus is necessary to establish infection in the arthropod vector

2 During extrinsic incubation in the vector, the period between ingestion and transmission by bite, the virus multiplies and reaches the salivary glands of the arthropod

3 The vector transfers virus to the vertebrate when it feeds on it

Vertebrate Host. One or more vertebrate species must be infectable by vector bite, and then virus must circulate in the blood stream in large amounts long enough to be provided to other vectors Biologically, this is the critical aspect of host-virus association The virus cannot be perpetuated if the vertebrate host cannot be infected by vector bite Characteristically, clinical manifestations need not accompany viremia, nor do clinical signs indicate previous or present intense viremia. Indeed, vertebrate species that support sub-

(Hammon, 1948; Reeves, 1958) and probably the dengue fevers (Smith, 1956) have adapted to new hosts and vectors By such adaptation they undoubtedly spread into geographic areas where their original hosts or vectors do not exist It is likely that this form of spread and subsequent host, vector or geographic isolation of the virus encourages antigenic variation from the parent strain of virus and in time results in a differentiable "type" This would explain the current differences and similarities of representatives within the A and B groups

One modification of the basic infection chain is characteristic of and unique, on the basis of present knowledge, to the tick-borne viruses (Silber and Soloviev, 1946, Florio and Miller, 1948) transmission of infection by female ticks through the egg to the subsequent generation This further assures survival of the virus

VERTEBRATE HOST
↓
TICK ─────┐
↓
TICK
↓
VERTEBRATE HOST ←┘
↓
etc

The implications of this adaptation are discussed in sections devoted to the tick-borne viruses (Chaps 14 and 18)

The preceding considerations of the factors controlling the life history of these viruses are essential to an understanding of the epidemiologic patterns of human infection

Epidemic Pattern. When infection is transmitted directly from man to man by an anthropophilic vector and the clinical attack rates are high, the epidemiologic characteristics and approach to study are similar in many ways to those of other epidemic virus diseases in a human population The cycle will generally be urban or domestic, because it depends on the availability and the close association of a large number of susceptible human hosts The infection will be epidemic and may involve all age groups Differences in susceptibility owing to age may distort the pattern if only overt infections are studied Continual transmission is essential to virus survival in the urban epidemic pattern Development of immunity by the host, decrease in the vector population or unfavorable climate may interrupt transmission

Variations in the virulence and the pathogenicity of these viruses may affect the epidemic pattern, as has been suspected and proved for other groups of viruses However, little is known of these characteristics of the arthropod-borne viruses in human infection under natural circumstances It remains for future studies to evaluate the epidemiologic significance of these virus characteristics

Human infection, immunity, population density and such factors are incidental to the survival of most arthropod-borne viruses, because they depend on other vertebrate hosts. A basic infection chain in lower animals may be active in areas with large human populations, even urban centers It may be diagrammed.

VERTEBRATE HOST
↓
VECTOR → MAN
↓
VERTEBRATE HOST

The entire proximal human population is at risk of being bitten incidentally by the infected vector If the human host does not have an adequate viremia or is not fed on by an effective vector, this chain reaches a "dead end" This type of cycle is exemplified by WEE, EEE, SLE, JBE, MVE, RSSE and Colorado tick fever Occasionally, some viruses might be transmitted from man to man several times and then die out because of limitations in host or vector On occasion there may be *contact infection between infected* animal hosts, as in VEE and EEE, or infection of man from contact with the infective discharges of animal hosts as in VEE Diphasic milk fever has adapted to animal hosts in such a way that transmission may be by arthropod vector or by milk

The epidemiologic pattern of incidental human infection with all the encephalitis viruses depends on the frequency of vector attack, the infectivity of the bite and the susceptibility of certain age groups to clinical infection Under optimal conditions for the virus, clinical attack rates of WEE, SLE and JBE may reach levels of 100 per 100,000 or above, even though the virus involved does

high enough for rapid extrinsic incubation and transmission (YF and dengue) in all seasons When these tropical viruses are introduced to temperate areas they may produce summer epidemics, but the onset of winter temperatures interrupts transmission. Having [illegible]

tribution of transmission by its direct effect on vector activities In temperate areas at low temperatures the vector may hibernate and interrupt or delay its feeding In the tropics during periods of prolonged high temperature and low rainfall the vector may go into a diapause phase and interrupt its feeding.

Levels of heat, humidity and rainfall affecting the reproductive cycle or longevity of vectors and vertebrate hosts will limit or increase the population and so decrease or accelerate transmission possibilities, through their influence on essential gross and microclimatic conditions Climate may even control the geographic distribution of the viruses as illustrated above.

Infection Chains. Bearing in mind the antigenic relationships of the arthropod-borne viruses and the biologic factors essential to their perpetuation, one suspects that phylogenetically they have evolved from relatively few prototypes The circumstances favoring such evolution may be clarified by diagramming a basic infection chain representative of the group and the possible variants

VERTEBRATE HOST
↓
VECTOR
↓
VERTEBRATE HOST
↓
VECTOR
↓
etc.

In the simplest model a single species of vertebrate host and of vector in close relationship maintain the virus All the epidemiologic factors of concern in other acute infectious diseases apply to the host, especially the number and the susceptibility of the population The vector replaces other means of transmission such as contact, mechanical vehicles, food or water. Transmission occurs if the virus is present, if there is a susceptible vertebrate population, if a large vector population effectively links the infective and susceptible host populations, and if the climate favors extrinsic incubation Examples of this type of infection chain are urban YF, dengue and phlebotomus fever.

Whether the infection is epidemic or endemic depends on the interaction of factors in the transmission cycle. It is immaterial to completion of the cycle whether infection in the vertebrate hosts is clinical or inapparent. The essential feature is that the infected host has sufficient viremia to infect vectors and that deaths or immunity responses do not reduce potential hosts to a level that interrupts the chain, causing the infection to disappear from the population.

Each virus survives in a basic infection chain In phlebotomus fever, epidemic dengue fever and urban YF, man is the vertebrate host, and *Phlebotomus pappataci* or *Aedes aegypti* are the only necessary vector species (Sabin, 1955, Taylor, 1951). However, one doubts that this is the basic infection chain for these viruses and suspects rather that the infection in man represents adaptation of the virus from a more basic chain, including a lower animal host and possibly another vector.

Probably man-to-man transmission of viruses by arthropods represents adaptation from another basic cycle, and they may also adapt to new vertebrate hosts other than man A new infection chain could develop if the vector were to transfer the virus to some other vertebrate host capable of supporting its survival Similarly, a new vector species may feed on the infected basic host and on subsequent feeding spread infection to its preferred host These possibilities may be diagrammed:

VERTEBRATE HOST	→	NEW VECTOR

Discovery of the true reservoir for one virus may clarify the problem with other members of the family.

Epidemiologic Tools and Procedures Epidemiologic study of the arthropod-borne viruses requires the services of a variety of professional specialists—physician, entomologist, virologist, vertebrate zoologist and veterinarian—and a well-organized virus laboratory

Proved clinical infections may be characterized in epidemiologic studies after diagnosis by virus isolation, serologic procedures and occasionally histopathologic or clinical procedures However, if studies are limited to clinical cases and epidemic periods, the true infection rate and basic transmission chain may remain obscure The extent of inapparent infection in man or other vertebrate hosts must be determined by serologic surveys for antibodies or tests for viremia Samples of arthropods must be tested for virus isolation to verify the vector species and their infection rates Frequently, findings must be confirmed by further study of the infection in vectors or hosts under controlled conditions

Current epidemiologic concepts have been formulated as a result of extensive application of these procedures and of detailed field studies of vectors and vertebrate hosts The development of control procedures for any of these virus infections must be based on knowledge of certain critical indices For the vector one would measure population, infection rate, infectivity rate by bite, and biting rates on vertebrate host species For host one would measure population, susceptibility and contact rate with the vector For climatic factors one would measure temperature and humidity and their effect on vector and host populations in the environment where transmission is expected

Control Control measures have been developed or considered for the relatively few infections of this group recognized as public health problems (Hammon, 1948, Smith, 1951; Sabin, 1955) Generally, efforts are directed either toward protection of susceptible hosts by immunization, as in YF, or toward vector control as in WEE, SLE, YF and dengue In addition, protection of individuals may be promoted by use of screens, repellents, or bed nets and isolation of clinical cases to prevent further vector infection All these measures may break vital links in the infection chain.

Immunization may be used selectively for members of a population under greatest risk of contact with vectors, or for an age group particularly susceptible to clinical infection Immunization has been used to protect man against YF and RSSE in rural circumstances and horses against WEE and EEE It can create a barrier if spread from person to person by vectors is feared, as in YF. However, for most of the viruses human immunization is still limited by lack of an effective vaccine, excessive cost, poor definition of the group at greatest risk, or ignorance of the period of greatest potential exposure (see Chaps 13 to 19)

Vector control is a promising approach if comprehensive epidemiologic study identifies the primary vector and proves it to be vulnerable to control and closely associated with man. In urban or domestic circumstances where a large human population is at risk of infection, reduction of the vector population may effectively interrupt transmission from person to person or reduce the risk of incidental spread of infection to man from a basic infection chain The feasibility of control may be limited by cost or by lack of knowledge of the vector's biology The ultimate effectiveness would be eradication of a vector from a geographic area, as is now being carried out for *Aedes aegypti* in areas of the Americas Under rural circumstances where man incidentally comes into contact with infected vectors, control may be impractical or impossible

Control through attack on the other vertebrate hosts in the basic chain has offered little promise for the few viruses with primary vertebrate hosts in a rural environment Inaccessibility of the hosts, economic or aesthetic value of the hosts and cost of control are prohibitive Conceivably in the future an ecologic approach may be developed in which the environment could be modified to control the host population

not depend on man for perpetuation. Clinical infections in man or other animals such as the horse are valuable indicators of virus activity, but as many infections remain subclinical the geographic extent of virus distribution cannot be measured solely on the recognition of clinical cases The basic infection chain may be active at such a low level and the vector attacks man so rarely that few or no human infections, clinical or subclinical, result This might best be referred to as a state of latent enzootic transmission

Endemic or Enzootic Pattern. Under endemic or more appropriately enzootic circumstances in rural areas, human infection may be limited to certain occupational, age or geographic groups, reflecting exclusive exposure of such groups or individuals to the vector in some other basic infection chain Man is usually a "dead end" in such a chain The circumstance seems to represent invasion by a susceptible host of an environment where risk of exposure to the vector is high Thus sporadic infection or disease may occur in middle-aged woodchoppers in endemic areas of YF (Taylor, 1951) or RSSE (Silber and Soloviev, 1946) and in agricultural workers in endemic areas of WEE (Longshore et al, 1956) Frequently, such cases are ascribed to a more common infection which produces similar symptoms.

Occasionally, endemic transmission occurs in urban or domestic centers where man is the only host In such circumstances the population is usually transient, with a constant immigration of susceptible people, or the majority of susceptibles are children in whom the disease is mild or atypical. A mixed susceptible and immune population where the vector population and climate are balanced may limit epidemic spread but is capable of supporting a smouldering endemicity (Taylor, 1951)

Reservoirs of Infection. A reservoir is a vertebrate or arthropod in which virus is maintained and can be disseminated for a prolonged period.

The tick-transmitted viruses have an effective reservoir because the vector is long-lived, remains infected for life and passes infection through the egg to at least a portion of its progeny. They can be maintained for long periods without vertebrate passage. In temperate areas the true "reservoir" status extends through winter. In contrast, vertebrate hosts of such viruses are infectious to ticks for only a few days.

Viruses transmitted by mosquitoes and sand flies have no apparent reservoir (Meyer, 1953; Reeves, 1958) The vectors may remain infective for life; but the adults are relatively short-lived except during hibernation or diapause, and there is no transovarian transmission In tropical areas a long-term reservoir may be unnecessary. Virus may persist by constant transmission whereby wandering epidemic or endemic centers maintain the contact of virus with nonimmune hosts and effective vectors. This idea has been challenged in recent years (Dick, 1953; Smith, 1956) The concept of wandering centers does not explain the persistence of virus in localities where a large proportion of hosts are immune and vectors are abundant, or persistence of infection through prolonged dry periods when vectors are few or inactive These circumstances in the tropics are comparable with temperate areas where viruses overwinter and show endemic persistence Possibly in temperate areas overwintering adult vectors maintain the virus, or occasionally vertebrate hosts have latent infections with intermittent viremia, or migratory hosts from more temperate areas reintroduce infection each summer (Hammon, 1948; Eklund, 1954, Reeves, 1958) Each possibility represents an extension in time or space of the basic infection chain

In current studies WEE and SLE viruses have persisted in experimentally infected *Culex tarsalis* through 3 winter months in a temperate area. The WEE-infected mosquitoes completed extrinsic incubation and could transmit infection (Bellamy et al, 1958). Both viruses have been isolated from naturally infected overwintering *Culex tarsalis* females during the winter and early spring when there was no evidence of active transmission (Reeves et al, 1958a, Blackmore and Winn, 1956). However, the pattern of virus occurrence indicated that latent virus infection in avian hosts was as likely to be the current source of vector infection as was the mosquito carrying infection through the winter WEE virus occasionally persisted in the organs of experimentally infected birds for 1 to 10 months (Reeves et al, 1958b).

WESTERN EQUINE ENCEPHALITIS

(SYNONYMS FOR EQUINE ENCEPHALITIDES OR ENCEPHALOMYELITIDES *Die Amerikanische Encephalitis [beim Pferde]*, epizootic equine encephalomyelitis, WEE)

INTRODUCTION

Western equine encephalitis is observed as a summer viral infection of lower animals, causing disease in horses and mules The virus is transmissible to human beings in whom a malady is produced closely resembling that of St. Louis encephalitis, but in its antigenic behavior the virus more closely resembles that of Chikungunya, a denguelike disease The disease is distinct in several features from the maladies caused by infection with the eastern and the Venezuelan equine viruses

HISTORY

For more than 75 years, epizootics of encephalitis have been observed in equine animals in the United States Meyer et al, *1931*, isolated the causal agent from the CNS of affected horses in California by inoculation experiments in which horses, monkeys, rabbits, guinea pigs, rats and mice were used The agent is now known as the western equine encephalitis virus Howitt, *1938*, was the first to recover the virus from the CNS tissue and blood of man by means of intracerebral inoculation of mice The most extensive human epidemic occurred in 1941, chiefly in North Dakota, Minnesota and adjacent provinces of Canada, over 3,000 persons were attacked with a mortality rate of 8 to 15 per cent At the present time, there exists an endemic focus over most of the western United States and particularly along the Pacific coast For example, in 1945 and 1946, there were 57 and 149 cases, respectively, diagnosed as neurotropic virus infections at the Kern County (California) Hospital, of these, 18 and 9 patients, respectively, were definitely shown to have had western equine encephalitis, from 1947 to 1951, the incidence was still low In 1952, however, an explosive epidemic erupted in the Central Valley of California, of 813 cases diagnosed as infectious encephalitis, 375 were confirmed by laboratory tests as western equine and 45 as St Louis encephalitis, as many as 100 cases of the former and 16 of the latter occurred in Kern County (Longshore et al, 1956) In the United States, in 1954, 1,075 horses and mules were attacked and 357 died

CLINICAL PICTURE

The incubation period is usually from about 5 to 10 days but may be 4 to 21 days. The clinical picture varies considerably in different patients, from negligible signs and symptoms to acute comatose states developing within 24 hours

In the severe type, patients exhibit prodromata of headache, drowsiness, fever and gastro-intestinal disturbances, this is the systemic phase, in many the disease process stops here In others, it continues and suddenly, sometimes gradually fever appears with neurologic signs and symptoms which consist of severe headache, insomnia, and marked pain in the muscles, especially those of the back Lethargy, disturbances of speech, ataxia, nystagmus, tremor, convulsions, mental confusion, amnesia, and even coma may supervene Paralysis is not common, occurring in about 15 per cent of those attacked, ophthalmoplegia and ptosis are still more uncommon The acute phase endures from 7 to 10 days Most patients recover completely, residuals such as parkinsonism are rare Clinically, it cannot be differentiated from St Louis and other forms of infectious encephalitis Abortive forms may be seen, here some of the prodromal symptoms, such as fever and headache, may be the sole indications of infection Clinically inapparent cases, i e, those in which no obvious signs except development of serum antibody are discernible, frequently are observed during epidemic and interepidemic periods

The white blood cell count during the encephalitic phase exhibits, as a rule, a slight polymorphonuclear leukocytosis, the total count ranges from 10,000 to 16,000 The cerebrospinal fluid shows a pleocytosis of 10 to more than 400 cells; early, polymorphonuclear leukocytes are in evidence, but about [illegible]

in amount

Arthropod-Borne Group A Virus Infections of Man

The history and the classification of the arbor viruses are given in the preceding chapter, the viruses of Group A and the diseases induced by them are discussed in this chapter. Certain concepts are defined that apply to this as well as to the other groups.

Of the several types of disease in most severe or typical form caused by arbor viruses (cf. Table 11, Chap. 12), denguelike, encephalitic and systemic syndromes are represented in Group A. Of these diseases, the encephalitides caused by western and eastern equine encephalitis viruses are of particular interest. They, as well as those caused by some Group B viruses (cf. Chap. 14), were designated by Hammon and Reeves, 1945, as "arthropod-borne viral encephalitides." This designation, proper when applied to the encephalitic syndrome, should not be extended to the causal virus itself. The concept that prevailed earlier, that the viral encephalitides were induced by agents designated as neurotropic (encephalitogenic) which attacked, as a rule, nervous tissue or neurons, has been gradually modified. In the natural history of the diseases and in the evolution of experimental infections, neurotropism has been found to depend on such variables as the species of the host, the strain of virus involved, its manipulation in the laboratory, and the route of inoculation in experimental infection. For example, the virus of yellow fever, which is viscerotropic in man in nature, can be made to exert a highly neurotropic action in mice; that of Venezuelan equine encephalomyelitis is neurotropic in laboratory animals but in man induces ordinarily a mild systemic infection. Yet, the encephalitides and the viscerotropic maladies and their viruses have many features in common, as was shown in the preceding chapter. One of the striking similarities is that the encephalitis can be considered generally as incidental or uncommon, and as will be shown later, the largest incidence of infections among the so-called "encephalitides" is clinically inapparent, abortive, or systemic.

The subject of human infections with arbor viruses, apart from yellow fever and dengue, has developed only during the last 25 years. From 1931 on, and in different parts of the world, approximately 50 viruses known or suspected of being arthropod borne have been discovered. Eight of these belong to Group A: western, eastern and Venezuelan equine encephalomyelitis, Semliki Forest, Sindbis, Mayaro, Chikungunya and Middelburg.

tissue with a sedimentation constant of 265 S or a diameter of 45 mμ; this component carried all of the infectivity. Studies on the chemical constitution of the infective particles purified by ultracentrifugation were reported by Beard, 1945, and colleagues (Sharp, 1953); the particle contained 54 per cent fat-solvent extractable material, 4 per cent carbohydrate and the remainder ribonucleoprotein. One should consider the limitations of a technic which may not yield a pure material (Sharp, 1953), the chemical results stated may need revision if more purified virus preparations become available. Electronmicrography of the virus is reported as revealing images resembling those of the active agent of papilloma, i e, round particles with ill-defined edges and internal structures, some dense, others vacuolated. The ultraviolet light adsorption spectrum of the purified virus is similar to that of nucleoprotein, inactivation of 10^6 infective units is reached in 13 minutes (lambda = 2,600 Angströms) at a radiation energy of 252 ergs/cm²/sec (Sharp, 1953). Ninety-nine per cent of the virus can be adsorbed on Willstaetter's type C aluminum hydroxide from which it can be eluted, Cox and Olitsky, 1934.

The maximum stability of the virus at icebox temperature is between pH 6 5 and 8 5, its infectivity is rapidly lost in suspensions more acid than pH 6 5. In suspensions, the virus withstands a temperature of 70° C, and in filtrates, a temperature of 60° C, for 10 minutes. In the preparation of vaccines, the virus is inactivated by keeping the suspension in the presence of 0 4 per cent formalin for 2 days at 20° C and then for 2 days at 4 or 5° C. It can be preserved in cold 50 per cent buffered glycerol at pH 7 4 or 7 5, by being held in the frozen state on dry ice, by lyophilization, or by being held in 2 per cent bovine serum albumin at −20 to −25° C, Olitsky et al, 1950, or in 60 per cent heat-inactivated rabbit serum, Olitsky et al, 1949.

The western virus grows readily in tissue cultures. Three findings with this virus as a model have led to important results. The first was made by Huang (1942, 1943) who observed cytopathogenesis in tissue cultures and its neutralization by immune serum which led to the development of improved technics for virus isolation and for antibody measurement (Syverton and Scherer, 1953; Fastier, 1954). The second finding was reported by Dulbecco (1952). In a monolayer of chick-embryo fibroblasts cultivated in vitro, plaques of necrotic areas appear, each presumably produced by one virus particle. This has become a useful technic for certain other viruses (Dulbecco, 1955; Dulbecco et al, 1956). The third finding was made by Trager (1938) who showed that this virus increases in titer when it is cultivated in the presence of mosquito tissue.

After natural or experimental infection, the virus induces a solid immunity, which can also be achieved by the use of vaccines consisting of virus inactivated by formalin as shown by Shahan and Giltner, 1934, Cox and Olitsky, 1936, Beard et al, 1940. Both complement-fixing (CF), virus-neutralizing (NT) and hemagglutination-inhibiting (HI) antibodies are associated with this immunity. Thus, in human beings ill with the infection, NT antibody is found within 7 days after the onset, it may persist for at least 12 years. CF antibody is also found within 7 days after the onset, but in the majority of cases it is not found 12 to 14 months after recovery, and HI antibody is first noted 1 to 7 days after onset of symptoms, much earlier than CF antibody. It is not yet known how long this persists. After vaccination of human beings, NT antibody lasts for at least 2 years, but little or no CF antibody is produced. In experimental animals after vaccination, NT antibody appears within 3 days and endures for at least 6½ months, CF antibody develops on the ninth day and lasts for at least 4 months, HI antibody is noted first within 7 days. The duration of antibody as stated is based on the longest time after vaccination at which tests were made.

Cox and Olitsky, 1936, and Morgan et al, 1942, demonstrated that mouse-brain vaccines can be used for the experimental production of solid and enduring immunity to challenge doses of the virus given intracerebrally and peripherally. In such vaccinated animals, there is correlation between the amount of NT antibody in the serum and the immunity against viral infection. This work points to the availability of antibody to the CNS as being an important factor in the manifestation of such

Pathologic Picture

Macroscopic and microscopic changes in the CNS closely resemble those of St Louis encephalitis and are essentially meningo-encephalitic, often the cord is not involved, although in some instances a few small lesions are seen in the upper cervical region As a rule, only a slight lymphocytic infiltration of the meninges occurs In the gray matter, there are widespread lesions consisting of focal accumulations of glial cells, perivascular lymphocytic infiltration, spongy disintegration of the ground substance, neuronal degeneration, and a varying degree of neuronal necrosis with neuronophagia A diffuse infiltration of polymorphonuclear and mononuclear cells may be observed The lesions are extensive in the gray matter, but scattered microglial aggregations and plaques of myelomalacia without a surrounding inflammatory reaction can be seen in the white matter Some blood vessels show an inflammatory reaction in their walls, and occasionally thrombi are seen

Experimental Infection; Host Range

The western virus has a very wide host range In nature, human beings, horses and mules have shown signs of infection, and the virus has been isolated, in addition, from *squirrels, deer, pigs and birds* The experimental infection with signs of illness can be induced by intracerebral inoculation in albino mice, hamsters, rats, guinea pigs, domestic and wild rabbits, monkeys, squirrels, cotton rats, kangaroo rats, wood rats, wild mice, young dogs, deer, pigs, gophers, calves, goats, prairie chickens and pigeons Sheep and cats are resistant Barnyard fowl and certain wild birds, after exposure to the virus by dermal inoculation, have a viremia but are otherwise unaffected (Hammon and Reeves, 1946, Hammon et al, *1951*) A viremia followed by CNS invasion is seen in the Syrian hamster which, in adulthood (*85* to 90 Gm.), is highly susceptible to peripheral (intramuscular, intraperitoneal, intracutaneous and subcutaneous) exposure *to the virus (de Boer et* al., 1955).

The animal of choice for many phases of experimental work is the white mouse. Old and young (15-day-old) mice are equally susceptible to the virus given intracerebrally and intranasally. Mouse-adapted virus, when introduced intracerebrally, produces disease in dilutions of 10^{-8} and rarely 10^{-10}; dilutions of 10^{-3} are effective by intranasal instillation From *2* to *6* days after inoculation, mice show signs of meningo-encephalomyelitis, e g, generalized spastic muscular contractions, spastic paralyses, wild or in-co-ordinated movements, torpor, prostration and death Death may ensue within a few hours after onset of signs or at any time up to *2* days later The pathologic picture simulates that observed in man After intraperitoneal or intramuscular inoculation of *15-day-old* mice, virus appears in the blood, and in the majority of instances, it migrates from the blood to the nasal mucosa, whence it invades the CNS by the olfactory route. Sabin and Olitsky, *1938*, showed that most old mice are resistant to the virus given by peripheral routes other than the nasal Newborn mice, on the other hand, are highly susceptible *to the* virus injected intraperitoneally *or subcutaneously, the titers being* similar *to those* obtained following intracerebral injection, Olitsky and Harford, 1938 With this virus, as well as with that of EEE, Hurst, 1936, reported that following infection of monkeys and guinea pigs, there is a visceral phase followed by a nervous one.

Chick embryos are highly susceptible to *this virus and* develop a characteristic rapidly lethal infection by all methods of inoculation, with titers between 10^{-7} and 10^{-9}. After inoculation by any route, the embryo dies within 18 *to 24* hours, showing widespread hemorrhage, thrombosis and necrosis throughout all tissues Half-day-old (not 1-day-old) chicks have been found to be highly susceptible to this and the eastern virus and are proposed *for use in* virus isolation *and* neutralization tests (Chamberlain, Sikes and Kissling, 1954).

Etiology

The diameter of the virus, estimated from results of filtration through gradocol membranes, is about *25* mμ; from electron microscopy and ultracentrifugation, about 40 mμ, by sedimentation, *57* mμ (Sharp, *1953*) It is filterable through Berkefeld V, N, and W and through Seitz filters Studies by ultracentrifugation on the virus grown in chick embryos, Beard, 1947, showed the presence of a component not present in the normal embryo

(1955a) also reported NT antibody in the plasma of domestic fowl The disease also occurs during the summer in Canada and the Argentine Republic, Causey and Theiler (1958) found NT antibody in 3 of 93 residents of the Amazon Valley, Brazil. In some outbreaks, victims of infection have frequently been adult males, 20 to 50 years of age, who work outdoors In the epidemic in Manitoba in 1941, a high attack rate was also noted in infants under 1 year of age. In the San Joaquin Valley in California, attack rates are highest in infants and children (Longshore et al, 1956) The mortality rate is said to be from 7 to 20 per cent, the average being about 10 per cent

There is solid evidence that the primary vector in the Western United States is a culicine mosquito, *Culex tarsalis* This mosquito has been found naturally infected in California, Washington, Nebraska, Montana, North Dakota, Minnesota, Colorado and Manitoba (Ferguson, 1954; Eklund, 1954), this mosquito is also a most efficient vector under experimental conditions (Hammon and Reeves, 1943, Barnett, 1956) and has a predilection for bird blood (Reeves and Hammon, 1944, Reeves et al, 1954) Birds, after infection by vector bite, show a viremia, their health otherwise being unaffected (Hammon and Reeves 1946) While virus has been isolated from several species of bird mites, it has not been possible to show transmission of the virus by their bite (Reeves et al, 1955, Sulkin et al, 1955, Chamberlain and Sikes, 1955) Hammon and Reeves, 1945, indicate that the vector may not be identical in all epidemic areas. Diverse mosquitoes, *Aedes, Anopheles* and *Culiseta*, have been found naturally infected or could be infected experimentally by feeding (Ferguson, 1954), and a wide range of wild and domestic bird species have been found with antibody following natural infection For all these reasons, Meyer (1953) considers that the ecology of infections in vertebrates could be exceedingly complicated Syverton and Berry, 1941, succeeded in transmitting the disease to animals by means of experimentally infected wood ticks, *Dermacentor andersoni*, ticks so infected could, in turn, convey, through transovarian passage, the virus to their progeny, however, there has been no epidemiologic evidence thus far that the tick is an important vector. The virus has been recovered from a cone-nosed bug, *Triatoma sanguisuga* (Kitselman and Grundman, 1940) caught in nature, however, this bug does not occur in most endemic areas. To conclude, the present concept of the spread of this infection and of St. Louis encephalitis is: An aviophilic mosquito conveys the infection from birds to birds as an inapparent infection, thus maintaining the virus in nature; and from birds to other vertebrates including man and horse, both of which are incidental hosts but can exhibit symptoms of disease (Hammon, 1948, Reeves, 1951) The overwintering reservoir of infection is unknown

The fact that man can be infected with WEE virus without having encephalitis is borne out by antibody surveys in areas where, as far as is known, serologic cross-reactions do not constitute a serious diagnostic problem. Some selected references are: Eklund (1946), who studied 173 sera during an epidemic in Minnesota deriving from persons giving no history of encephalitis and found 3, or 1 7 per cent, positive Hammon and Reeves (1947) in an endemic area of Washington, of 151 sera from persons without a history of encephalitis, found that 12, or 8 per cent, were positive. The findings of La Veck et al (1955) should be described in detail 614 sera were collected from persons in Weld County, Colorado, where human and equine cases arose from 1937 through 1949, and the virus was isolated repeatedly from birds and mosquitoes in the 5 years prior to the survey. Of the sera, 67, or about 11 per cent, had NT antibody, later it was found that a positive reactor had had encephalitis 15 years earlier, but none of the other 613 persons had a history of CNS illness. Hence, one can conclude that about 11 per cent of this population in an endemic area responded to infection without clinical manifestations (inapparent infection)

Control Measures

Control measures can be directed either toward preventing dissemination of the virus through an attack on the mosquito vector or toward increasing the resistance of the exposed group through immunizing procedures The former method has been advocated and used extensively in certain endemic areas

immunity. Vaccination of guinea pigs to a degree at which they resist 1,000 cerebral lethal doses fails to protect the CNS against the initial effects of the virus given intracerebrally, an abortive infection of 20 to 30 hours' duration ensues, characterized by fever and histopathologic changes simulating those which occur in control animals at a very early period after infection. In addition, recovered guinea pigs or mice are resistant for about 2 weeks to certain heterologous agents, such as eastern equine and vesicular stomatitis viruses, given intracerebrally. This appears to be an interference phenomenon, Schlesinger et al, 1944 Schlesinger, 1949, has found that vaccinated mice may be resistant to large intracerebral inocula of a slowly growing strain of the virus but not to a rapidly growing derivative Also, if their immunity is of a low grade, they are more resistant to a large than to a small amount of virus, a result, perhaps, of the antigenic booster effect of the excess of virus in the large inocula. Fastier (1952) suggested that the virus given intravenously in young (10 to 15 Gm) mice exhibits toxicity which can be neutralized by specific antiserum

Diagnosis

As with other arbor viruses, the type of disease can only be determined by isolation and identification of the virus or by serologic and immunologic tests. the laboratory procedures involved in diagnosis have been described (cf Chap 10) For general diagnostic use, the CF test is advised, with it, overlapping of WEE antibodes with other Group A viruses is not marked In addition, the slower rate of development of CF as compared with NT or HI antibodies more often permits the demonstration of conversion from negative to positive reaction with paired sera from patients Lennette et al. (1956) called attention to the value of a chick-embryo-derived antigen for CF tests For attempts to isolate virus, the most satisfactory source of virus is CNS tissue; even though this virus has been recovered from the blood and the cerebrospinal fluid of patients, it has been found so rarely as to make viral studies on such material inadvisable as a diagnostic measure.

Treatment

There is no specific treatment of the disease, supportive measures are indicated and essential, and good nursing care is of the utmost importance (Longshore and Maranda, 1956). Olitsky et al., 1943, have shown in experiments with mice and guinea pigs that hyperimmune rabbit serum is ineffective if treatment is begun after onset of definite signs of encephalitis; however, if the antiserum is given to guinea pigs 24 to 48 hours after inoculation of virus and before the signs of disease are obvious, treatment can prevent lethal infection (For experiments with hamsters, see de Boer et al, 1955.) Moreover, in certain serum-treated animals there occurred typical, fatal encephalitis after an incubation period of 13 to 47 days, in such instances, it was assumed that the virus persisted within the CNS during the prolonged incubation period, and when the content of antibody of the CNS reached a low level, even though still demonstrable, it became ineffective and could no longer prevent the active agent from pass- [illegible] fecting other cells These findings

Rivers, 1939, that treatment with immune sera is, with few exceptions, valueless if it is begun after onset of definite clinical signs of a viral infection Sulfonamide compounds and ACTH do not affect the virus or the experimental disease induced by it (Olitsky and Saenz, 1948)

Epidemiology

The main epidemiologic features of the disease are similar to those of St Louis encephalitis, indeed, mixed epidemics have been reported Epidemics of the disease and poliomyelitis have occurred simultaneously in the same area as was the case in Manitoba during the summer of 1941, when, without serologic tests, it was not easy to differentiate one infection from the other, similar mixed epidemics have occurred in western areas of the United States The disease prevails chiefly from early June to mid-September in the United States west of the Mississippi River; equine cases have been reported, in addition, [illegible] and Alabama, and the virus has

1,000 cells among which polymorphonuclear cells predominated during early stages and mononuclear cells later Protein was increased, *but sugar was normal in amount.*

The severity of the disease when clinically

the majority of survivors had sequelae of variable severity However, there are a certain number of human beings who, as first shown by Olitsky and Morgan, *1939*, develop no clinical reaction after infection with the virus but show specific NT antibody (see below).

Pathologic Picture

On macroscopic examination of the 1938 Massachusetts cases, generalized visceral congestion and pulmonary edema were observed The brain showed marked congestion, edema and flattening of the convolutions. On microscopic examination, inflammation of the meninges was noted, and lesions were found to be widespread throughout the brain but mainly in the brain stem and basal ganglia, the cord often being spared or exhibiting only mild changes The pathologic changes in the nervous tissue consisted of severe destruction of neurons and ground substance, perivascular cuffing, and plaques of encephalomalacia In acute cases, the infiltrating cells were polymorphonuclear leukocytes, in patients who succumbed a week after onset of illness, mononuclear cells predominated Small blood vessels revealed disorganization of their walls and endarteritis with deposition of fibrin and formation of thrombi

Experimental Infection, Host Range

The EEE virus is, in general, more invasive and has a greater degree of virulence in experimental animals than has the virus of WEE, this is reflected by a shorter incubation period, more rapid death and often a higher titer of virus in the CNS tissues For example, adult mice are killed within 2 or 3 days after intracerebral exposure to the virus. Otherwise, it induces an experimental disease similar to that caused by the western virus, and the host range is also similar with the exception that cats, hedgehogs, quail and sheep have been shown to be susceptible to the virus given intracerebrally (see above, western equine encephalitis). Of special interest for its epidemiologic implications is the susceptibility to this virus exhibited by a

inoculation or by bite of infected mosquitoes Some of the birds, among which were the white ibis and the purple grackle, developed only subclinical infections with viremia; others, like cardinals and sparrows, developed a fulminating infection with death within 48 hours

Etiology

The properties of EEE virus are, in general, similar to those of WEE virus (see above) Studies by Beard, 1945, and Sharp (*1953*) showed that the infective component of this virus, purified by ultracentrifugation, has a sedimentation constant of 273 S instead of 265, which was found for WEE virus It was also reported by Beard, 1945, that the number of particles of EEE virus per 0 05 cc necessary for infection of mice is 250 However, it should be borne in mind that the validity of such figures necessarily depends on the purity of the preparation being studied (see above, WEE) Bang and Gey, *1949*, found by electron microscopy diplococcuslike bodies in chick-embryo cultures of the virus, similar to those described by Beard in purified preparations of the same agent. The same authors (1952) noted in roller-tube cultures of rat cells deriving from different types of mesenchymatous tissue varying susceptibilities to the virus, some showing slight, others complete destruction, cells of intermediate susceptibility supported virus growth after a single inoculation for over 4 months and developed such minimal changes as not to exceed those seen in uninfected cells This is significant in view of the long persistence of certain viruses in some hosts apparently otherwise unaffected TenBroeck and Herriot reported, 1946, that the active agent is inactivated by one of the mustard compounds, bis(beta-chloroethyl) sulfide, without losing its antigenicity. It could be maintained in 5 per cent guinea pig serum plus 0 1 per cent cysteine

(*Reeves, 1951, Reeves et al, 1952; Stead and* Peters, 1953) A formolized vaccine made from nervous tissue of animals was prepared by Shahan and Giltner, 1934, and Cox and Olitsky, 1936. A formolized chick-embryo vaccine is available for the prevention of the disease in equine animals, Beard et al, 1940 It has received the approval of the U S Bureau of Animal Industry as an effective means of prophylaxis. Recommendations concerning the use of such a vaccine in man await the results of controlled tests in the field under epidemic conditions In the meantime, it is being used for workers in laboratories or those especially exposed to the virus. Specific antiserum for passive immunization has been used successfully in experimental animals, but no satisfactory trial has been made in human beings Studies by Morgan, 1941, and Schlesinger et al (1942) show that prevention of peripheral infection of mice could be achieved when small amounts of serum antibody were present (cf de Boer et al, 1955) Sabin (1951) reported that passive (intravenous) transfer of antibody sufficient to yield an intracerebral neutralization index of ca 50, protected mice against 400 to 4,000 intraperitoneal doses (equal to 2 million mouse intracerebral LD_{50}) of virus Hence, the minimal dose of antibody that might perhaps be considered for trial in human beings should be enough just to show itself in undiluted serum at the end of the period of the individual's exposure—a situation applying, perhaps, to other arbor viruses

EASTERN EQUINE ENCEPHALITIS

(SYNONYMS Similar to those for western equine encephalitis, EEE)

INTRODUCTION

Eastern equine encephalitis is a summer disease of equine and avian animals, which is transmissible to man in whom it can produce extensive inflammation and destruction of CNS tissue

HISTORY

During the summer of 1933, TenBroeck and Merrill recognized an encephalitis in horses on farms in Virginia, Delaware, New Jersey and Maryland. These workers and, at about the same time, Giltner and Shahan, 1933, isolated a new virus from the brains of affected animals, which was designated eastern equine encephalitis virus It was first recovered from human CNS tissue by Fothergill et al, 1938, and Webster and Wright, 1938, from fatal cases of an epidemic that occurred that year in Massachusetts In this epidemic, the first on record, at least 34 persons, mostly children, were involved with a mortality rate of 74 per cent. In the same area and at the same time, 90 per cent of 248 horses which had encephalitis died Subsequently, small but usually severe outbreaks have occurred in man in different localities. Thus, in Louisiana in 1947, at least 15 cases with 9 deaths were reported at the same time that an epizootic occurred in horses of which 90 per cent of 14,000 died In the Dominican Republic in 1948-49, 9 deaths occurred among 13 persons affected, also shortly after an equine outbreak had begun during which 516 cases in horses were reported (Eklund et al., 1951) Additional, sporadic cases, or smaller outbreaks, have been reported in Texas (1941-42) and Massachusetts (1955)

CLINICAL PICTURE

In general, the clinical picture has been similar to the one first described for the 1938 Massachusetts epidemic by Farber et al, 1940, and Ayres and Feemster, 1949 On that occasion, the disease was severe and fulminating As a rule, there were two phases The first, or systemic phase, began suddenly with nausea, vomiting, headache and fever which lasted 24 to 36 hours and was followed by a short period of well-being After this came the second, or encephalitic phase, with high fever reaching 106° F at times, gastro-intestinal disturbances, drowsiness or coma, convulsions, generalized rigidity or opisthotonos, paralyses, bulging fontanelles, edema of legs and face, and cyanosis As a rule, the acute manifestations lasted about a week, extremes being from 1 day to 3 weeks Of the survivors, only 1 recovered completely; the others exhibited sequelae varying from emotional instability to various types of paralyses and mental deterioration

Leukocytosis of 14,000 to 66,000 cells, of which 90 per cent were polymorphonuclear, was present The cerebrospinal fluid was under increased pressure with a pleocytosis up to

1,000 cells among which polymorphonuclear cells predominated during early stages and mononuclear cells later. Protein was increased, but sugar was normal in amount

The severity of the disease when clinically diagnosable as encephalitis is indicated by the fact that in 4 outbreaks (2 in Massachusetts, and 1 each in Louisiana and Dominican Republic) of 66 persons affected, 44 died; and the majority of survivors had sequelae of variable severity However, there are a certain number of human beings who, as first shown by Olitsky and Morgan, 1939, develop no clinical reaction after infection with the virus but show specific NT antibody (see below).

Pathologic Picture

On macroscopic examination of the 1938 Massachusetts cases, generalized visceral congestion and pulmonary edema were observed The brain showed marked congestion, edema and flattening of the convolutions On microscopic examination, inflammation of the meninges was noted, and lesions were found to be widespread throughout the brain but mainly in the brain stem and basal ganglia, the cord often being spared or exhibiting only mild changes The pathologic changes in the nervous tissue consisted of severe destruction of neurons and ground substance, perivascular cuffing, and plaques of encephalomalacia In acute cases, the infiltrating cells were polymorphonuclear leukocytes, in patients who succumbed a week after onset of illness, mononuclear cells predominated Small blood vessels revealed disorganization of their walls and endarteritis with deposition of fibrin and formation of thrombi

Experimental Infection, Host Range

The EEE virus is, in general, more invasive and has a greater degree of virulence in experimental animals than has the virus of WEE, this is reflected by a shorter incubation period, more rapid death and often a higher titer of virus in the CNS tissues For example, adult mice are killed within 2 or 3 days after intracerebral exposure to the virus Otherwise, it induces an experimental disease similar to that caused by the western virus, and the host range is also similar with the exception that cats, hedgehogs, quail and sheep have been shown to be susceptible to the virus given intracerebrally (see above, western equine encephalitis) Of special interest for its epidemiologic implications is the susceptibility to this virus exhibited by a number of domestic and wild birds, pheasants have been shown to be highly reactive to subcutaneous or oral exposure to the virus. Kissling et al. (1954) found 8 species of wild birds susceptible to the virus either by subcutaneous inoculation or by bite of infected mosquitoes Some of the birds, among which were the white ibis and the purple grackle, developed only subclinical infections with viremia; others, like cardinals and sparrows, developed a fulminating infection with death within 48 hours

Etiology

The properties of EEE virus are, in general, similar to those of WEE virus (see above) Studies by Beard, 1945, and Sharp (1953) showed that the infective component of this virus, purified by ultracentrifugation, has a sedimentation constant of 273 S instead of 265, which was found for WEE virus It was also reported by Beard, 1945, that the number of particles of EEE virus per 0 05 cc. necessary for infection of mice is 250 However, it should be borne in mind that the validity of such figures necessarily depends on the purity of the preparation being studied (see above, WEE). Bang and Gey, 1949, found by electron microscopy diplococcuslike bodies in chick-embryo cultures of the virus, similar to those described by Beard in purified preparations of the same agent. The same authors (1952) noted in roller-tube cultures of rat cells deriving from different types of mesenchymatous tissue varying susceptibilities to the virus, some showing slight, others complete destruction; cells of intermediate susceptibility supported virus growth after a single inoculation for over 4 months and developed such minimal changes as not to exceed those seen in uninfected cells This is significant in view of the long persistence of certain viruses in some hosts apparently otherwise unaffected. TenBroeck and Herriot reported, 1946, that the active agent is inactivated by one of the mustard compounds, bis(beta-chloroethyl) sulfide, without losing its antigenicity. It could be maintained in 5 per cent guinea pig serum plus 0 1 per cent cysteine

hydrochloride for at least 11 years at 4° C. (Labzoffsky et al., 1955).

Morgan, 1941, found that following extraneural injection of EEE virus to young and old mice, the capacity to be immunized increased with the age of the animal, i.e., old mice produced a higher level of antibody at a more rapid rate than did young ones With EEE and WEE viruses, Olitsky et al., 1936, and Sabin and Olitsky, 1939, demonstrated in mice and guinea pigs the development with age of resistance to the effects of peripheral inoculation

Diagnosis

Specific diagnosis of the infection can be made only by laboratory procedures The virus has been isolated from the blood of birds naturally infected and of sentinel monkeys. All recorded isolations of the virus from human beings are from CNS tissue, it is conceivable that blood taken at the time of viremia, preceding CNS involvement, might yield the agent.

Treatment

No specific treatment is available Sulfonamide and antibiotic compounds are ineffective in experimental infections

Epidemiology

The disease in horses and mules is, at present, distributed over the eastern part of the United States and Canada (Ontario), Mexico, Brazil, Panama, Cuba and the Dominican Republic In pheasants, the infection is prevalent in the northeastern states, particularly New Jersey where, between 1939 and 1954, 27 epizootics have been reported (Beaudette et al, 1955) The virus has been isolated from a monkey in the Philippine Islands In man, clinical infection with EEE virus has been reported in Massachusetts, Texas and Louisiana and in Cuba and the Dominican Republic Human outbreaks usually have been preceded or accompanied by epizootics in horses, this was the case in Massachusetts in 1938, Louisiana in 1947, and in the Dominican Republic in 1948-49 In Massachusetts, during July through October, 1938, the disease attacked human beings and horses, the median date for reported deaths in horses was August 27, 2 weeks earlier than a similar date for human deaths The majority of cases in this epidemic occurred in young children and infants, 70 per cent were under 10 years, 25 per cent less than 1 year; both sexes were attacked equally. During the fall, the disease was detected in pheasants and a pigeon caught in the same area.

The severity of the clinical disease in the United States has been mentioned already (see above), it is also worthy of note that evidence of subclinical infection with this virus in northeastern United States has not been reported, in general, Fothergill (1939) failed to detect neutralizing antibodies in the serum of 114 persons, many of whom were contacts. Similarly, Liao (1955) found no antibodies in the serum of 215 pheasant farmers and handlers after a severe epizootic in pheasants in Connecticut However, neutralizing antibodies have been detected in other localities in the absence of encephalitis, indicating that subclinical or aberrant infections occur; surveys carried out shortly after epidemic outbreaks showed neutralizing antibody in Louisiana in 4 of 45 persons (Howitt et al., 1948); in the Dominican Republic in 32 of 827 (Eklund et al, 1951). In addition, antibodies have been detected in instances where no association with an outbreak was apparent, as reported by Schaeffer et al (1954), in Louisiana with 4 positive of 69 tested, and by Causey and Theiler (1958) in Brazil with 16 positives among 326 persons The fact that in northeastern United States no positive sera were found of 329 tested (cf Fothergill and Liao), while in the Dominican Republic 32 of 827 were positive and in Brazil, 16 of 326, may point to differences in epidemiologic patterns

Merrill et al., 1934, showed that EEE virus multiplies in *Aedes sollicitans* mosquitoes while WEE virus multiplies in *Aedes aegypti*, thus demonstrating for the first time multiplication in mosquitoes of a virus derived from animals. Chamberlain et al (1954) investigated the experimental vector potential for EEE virus of about 20 different species of mosquitoes, on the basis of thresholds of infection, infection rates and transmission rates for each species, certain mosquitoes (*Aedes aegypti*, *A sollicitans* and *A. triseriatus*) are considered more likely to be active vectors than others

The vector in nature is not known The

virus has been isolated from the following wild caught mosquitoes; *Mansonia perturbans*, by Howitt et al. (1948), *Culiseta melanura*,

chicken mites (*Dermanyssus gallinae*) and a mixture of lice (*Eomenacanthus stramineus* and *Menopon pallidum*) It is worthy of note that, in endemic areas in the United States, the frequency of isolations of EEE virus from wild caught arthropods is far lower than that of other arbor viruses, i e, WEE and St Louis, in their endemic areas

Studies on the possible reservoir of the virus in nature, by TenBroeck in 1938 and 1940, led to the conclusion that birds are more likely than horses to act as reservoir hosts Additional experimental evidence pointing in the same direction has been offered by Kissling et al (1951), who found several species of wild birds to be susceptible to this agent, the birds developed viremia without other signs of illness Furthermore, EEE virus has been isolated in nature from the blood of birds on four occasions purple grackle (Kissling et al., 1954), loggerhead shrike, cardinal and Carolina chickadee (Kissling et al, 1955) The observations by Kissling et al (1954) that antibody that developed in birds after naturally acquired infection was transmitted to nestlings via the ovary, and a similar observation by Reeves et al (1954) for WEE and St Louis viruses might indicate a possible mechanism for limiting the natural spread of infection among nestling birds

The present estimate of the situation prevailing with EEE virus infection concerning reservoir-vector-host relationship is summarized by Schaeffer and Arnold (1954) in their review of the result of a 5-year study Equine animals are probably a "dead end" in the infection chain, and transmission to human beings is only occasional and incidental Birds and mosquitoes remain important in the natural history of the infection, while the role of mites or other ectoparasites is considered of minor or probably no importance.

A particularly interesting aspect concerning the dissemination of this virus in nature is presented by outbreaks in pheasants From the mode of spread of the disease which affects nearly all the birds in one pen while failing to affect birds in adjacent pens, in addition to the fact (Holden, 1955b) that pheasants can be infected by ingestion of the virus, it would appear that the epidemiologic cycle in the pheasant can be completed without an insect vector.

Control Measures

Specific antiserum prevents the disease in experimental animals, its use as a prophylactic measure in man must await further tests Formalin-inactivated vaccines prepared from infected chick embryos, Beard et al, 1940, have been used successfully for prevention of the disease in equine animals The general principles of active immunization with such vaccines were described by Olitsky and Cox, 1936, and by Cox and Olitsky, 1936 While the vaccine has not as yet had a trial in human beings in the face of an epidemic, it has been given to persons who from the nature of their work are exposed to the virus, as yet it is not recommended for mass immunization of human populations Hurst et al (1952) stated that the antimalarial mepacrine (atabrine) inhibits multiplication of the virus and is, perhaps, a preventive of the experimental disease in mice, however, after definite lesions have developed, it is ineffective Mosquito control should be considered in any program for prevention of the disease

VENEZUELAN EQUINE ENCEPHALITIS

(Synonyms Peste loca; VEE)

Introduction

Venezuelan equine encephalitis is observed as a disease primarily of equine animals, its causal agent is transmissible to human beings in whom it usually induces a mild disease of variable syndrome, rarely, if ever, associated with frank encephalitis

History

During 1935, an encephalitis was observed in horses and mules in Colombia In 1938, a severe epizootic swept over Venezuela, the agent responsible for this outbreak was recovered by Beck and Wyckoff, 1938, and by Kubes and Rios, 1939, from the brains of animals that had died of the disease Later, the virus was reported in Ecuador, Trinidad,

Panama and more recently (Causey and Theiler, 1958) in Brazil. Human infections have been described by Casals et al, 1943, and by Lennette and Koprowski, 1943, they occurred in laboratory workers and were mild, other laboratory infections have been reported in Argentina in 1944. Two fatal encephalitic infections of man, possibly due to VEE virus, occurred in 1943 in Trinidad and were described by Randall and Mills, 1944, and Gilyard, 1945 In the Colombian epidemic of 1952, at first the cases were diagnosed as a denguelike fever (Sanmartin-Barberi et al, 1954)

Clinical Picture

The precise incubation period is unknown; it is probably short, from 2 to 5 days As a rule, persons infected with this virus during laboratory investigations do not show neurologic or encephalitic signs but a picture similar to influenza, generally with mild symptoms, headache and fever are prominent, also gastrointestinal disturbances. Only in rare instances are tremor, myalgia, diplopia and lethargy noted Signs and symptoms persist for 3 to 5 days in mild cases and for 8 days in more severe attacks, after which prompt and complete recovery takes place In the 2 cases in Trinidad, acquired under natural conditions, the onset was acute with definite symptoms of encephalitis which were followed by coma and death In the epidemic in Colombia in 1952, *perhaps as many as 70 cases occurred*, the clinical picture as subsequently reconstructed was marked by sudden onset with malaise, chills and fever, nausea, vomiting, headache, muscle and bone pains Fever lasted from 1 to 4 days, and complete recovery ensued Little is known as yet concerning changes in the blood and the spinal fluid.

The pathologic picture in human beings has not been sufficiently studied to warrant comment, while in the experimental disease of guinea pigs, rabbits and mice, a lymphomyelopoietic necrosis is seen and encephalomyelitis is noted in monkeys and mice The necrosis involves all lymphoid and myeloid tissues, and the CNS lesions are not much different from the general picture in animals produced by other arbor viruses (Victor et al, 1956). The horse, which usually shows pancreatic lesions, is susceptible to intranasal instillation of the virus; infected animals shed virus from the nose, the eyes, oral secretion, urine and milk; they can infect by contact (Kissling et al., 1956).

Experimental Infection; Host Range

In addition to equine animals, the virus is pathogenic by intracerebral route for mice, guinea pigs, rabbits, rats, dogs, cats, sheep, goats, and partially so for pigeons Chick embryos are susceptible. Cattle are resistant A distinctive feature of the virus is its high virulence for adult animals when inoculated by peripheral (non-neural) routes, when administered in this way, as little as 10^{-9} or 10^{-10} dilutions of mouse-adapted virus may infect mice. This species responds to intracerebral introduction of the virus with a disease that is transmissible to normal mice by contact in cages. Such infected mice harbor the virus in the tracheopharyngeal washings and the feces but not in the urine In the natural disease of man, the virus had been found in the CNS and also in the blood. The active agent is recovered not only from the nasopharynx of human beings infected accidentally in the laboratory but also from their blood; this is a characteristic feature of the malady It is important to recognize that this virus actively infects human beings as well as experimental animals exposed to it in laboratories.

Etiology

Little is known of the properties of the virus. It is not readily inactivated by formalin in vaccine preparation (see below). It is filterable through Berkefeld N and Seitz filters; it can be preserved in 50 per cent buffered glycerol by being held in the frozen state at $-70°$ C and by lyophilization It grows well in the Maitland type of tissue culture and in embryonated hens' eggs; active growth is possible in human and canine uterine tissue cultures (Gajdusek et al, 1954) and in HeLa cells (Murphy et al, 1955) Convalescent human beings and animals immunized with vaccines develop specific NT, CF and HI antibodies, they appear from 1 to 2 weeks after onset of infection, but how long they endure is still to be determined

Diagnosis

A specific diagnosis can be made only by laboratory procedures, *i e., by identification*

of the virus isolated from CNS tissue, blood or nasopharyngeal washings, or by finding HI, NT or CF antibodies during convalescence

Treatment

There is no specific treatment

Epidemiology

The known distribution of the natural disease or of the virus is, at present, in northern South America, the Amazon Valley, Trinidad and Panama The reservoir of the virus is still to be found Its mode of transmission in man may vary, in certain instances, such as in laboratory infection, it may be by droplet or dust infection Gilyard, 1944, considers that *Mansonia titillans*, a culicine mosquito, and *Aedes taeniorhynchus* may transmit the disease to horses and human beings Wild birds can be infected by subcutaneous inoculation and by bite of infected *Aedes triseriatus* (Chamberlain et al, 1956), the infection is nearly always inapparent or silent This mosquito can act as a vector in transmission experiments with English sparrows, owing to the low level of viremia, Chamberlain et al (1956) consider the role of birds in this disease uncertain but capable of contributing as a source of infection for the mosquito in the cycle mammal-mosquito Since man may become infected through the upper respiratory tract and since the virus is found in the nasopharyngeal washings of infected human beings, it is conceivable that epidemics may occur without the aid of an insect vector The extent of inapparent infection by this virus is brought out by the studies of Downs et al (1956), which revealed that 6 9 per cent of 160 sera deriving from healthy residents of Trinidad without a history of encephalitis had neutralizing antibodies against VEE virus, and by Causey and Theiler (1958), who found that 16 per cent of 30 similar sera from persons in the Amazon Valley also contained neutralizing antibodies

Control Measures

A formalin-inactivated vaccine prepared from infected chick embryos, Kubes and Rios, 1939, has been used in Venezuela for prevention of disease in horses Randall et al, 1949, prepared a partially purified vaccine which has been shown to produce a high level of antibody. This vaccine has been used only for protection of laboratory workers, Smadel, 1951 A similar vaccine of the 3 types of the equine viruses was prepared later at the United States Army Medical School (Maurer et al, 1952). However, Sutton and Brook (1954) have drawn attention to an important finding which may apply to other viral vaccines. Of those receiving the formalinized Venezuelan virus, 14 of 327 persons (1,174 inoculations) became ill, and 8 of 10 tested yielded this virus Two points are brought out: (1) either the tests for active virus in the vaccine were inadequate, or (2) man is more susceptible to the virus than are the laboratory animals used in the tests Any program for prevention should include insect control

SEMLIKI FOREST VIRUS

(Synonyms: Semliki virus, Kumba virus)

The Semliki Forest virus was first isolated by Smithburn and Haddow, 1944, from a group of *Aedes abnormalis* mosquitoes caught in Uganda To the present time, the virus has been recovered twice from mosquitoes, no human disease caused naturally by it has been reported, nor has the virus been isolated from man

The available strains of virus are pathogenic for mice when introduced into them intracerebrally or peripherally, viremia develops, followed by encephalitis characterized by lesions resembling those of the equine encephalitis viruses Guinea pigs, rabbits, rhesus and red-tail (*Cercopithecus nictitans*) monkeys are susceptible to intracerebral but not to peripheral inoculation of the virus The virus can be propagated in golden hamsters, chick embryos and in tissue cultures (Ginder and Friedewald, 1951)

The virus has been reported to be unusually resistant to heat, and 60° C for 1 hour is needed for its inactivation Its size as determined by gradocol-membrane filtration is 15 to 30 mμ It is cytopathogenic in and destroys the tissue of rabbit fibromata; it is also cytopathogenic in tissue cultures thereof, even though the active agent is nonpathogenic for rabbits by peripheral routes of exposure (Ginder and Friedewald, 1951). The antibiotic helenine derived from *Penicillium funic-*

ulosum was found to modify experimental infection in the mouse (Shope, 1953).

Within Group A, Semliki virus is more closely allied serologically to Chikungunya and Mayaro viruses than to the other agents of the group. Owing to this close serologic relationship, antibodies found in nature either in man or in animals, capable of reacting with Semliki virus, must be interpreted with caution until their specificity is ascertained. Antibodies in man capable of neutralizing Semliki virus have been reported in Uganda (Smithburn et al., 1944), Malaya and Borneo (Smithburn, 1954), India (Smithburn et al., 1954), South Africa (Kokernot et al., 1956) and Brazil (Causey and Theiler, 1958). On the basis of HI tests using an antigen developed by Clarke and Theiler (1955), it would appear as though the antibodies found in Brazil can best be explained by the presence of Mayaro virus in that country (Casals and Whitman, 1957). Limited information indicates that, in some cases, human sera from Africa and Malaya having neutralizing antibodies against Semliki virus react by HI test to a considerably higher titer against Chikungunya than against Semliki virus.

CHIKUNGUNYA DISEASE

Introduction

Chikungunya is a newly described human disease first noted in 1952-1953 in Tanganyika. It takes its native name from its outstanding symptom, i.e., a state of being "doubled-up" owing to fulminating, severe joint pains that compel this striking posture.

History

An outbreak of a denguelike malady arose in the Makonde Plateau, Newala district of southern Tanganyika. A virus was isolated repeatedly by Ross (1956) from patients' blood in the acute phase, also from wild caught mosquitoes. The incitant was then shown to be a new member of Group A arbor viruses (Spence and Thomas, 1958). Recently, additional strains have been recovered from the blood of an African mosquito catcher in the Zika forest near Entebbe, Uganda; and from human cases of denguelike disease in the Union of South Africa (Smithburn, 1957).

Clinical Picture

The following account derives from Robinson's (1955) observations on 115 hospitalized patients and on a number of other affected individuals. The incubation period is 3 to 12 days. The onset is sudden with excruciating pains in the joints, the patients being incapacitated within a few minutes or hours from the onset. A rapid rise of temperature to 102° to 105° F. supervenes, and the victim assumes a doubled-up position and becomes immobile, hence, the name of this illness. The pains occur in the limbs and the spine, but headache is usually mild, and no eyeball or postorbital pains, as found in dengue, are noted, although anorexia and constipation occur. After 1 to 6 days of fever, an apyrexial period of 1 to 3 days is followed in most patients by another less intense fever. At this recurrence, or thereafter, a rash is seen in about 80 per cent of individuals, which is maculopapular, pruritic and present on the trunk and on the extensor surfaces of the limbs. The malady in this acute stage endures 6 to 10 days, but in several persons apyrexial joint pains recur intermittently over a period up to 4 months, and at times they practically cripple the victim. No second attacks have been known to arise, no deaths have been ascribed to the disease. The blood reveals a leukopenia of 4,000 to 5,000 cells. No pathologic reports on patients or experimental animals are as yet available.

Experimental Infection; Host Range

The virus is pathogenic for suckling mice after intracerebral or intraperitoneal inoculation. The LD_{50} titer by the former route is 10^{-7}, and the incubation period 2 to 5 days. Adult (28-day-old) mice were not as highly susceptible (Ross, 1956) even when the suckling-mouse-adapted strain in its 100th passage was given, but with the 160th passage they developed a lethal infection with only a few survivors; the titer was 10^{-6}, and the incubation period 4 to 8 days; they succumbed after 3 to 5 days. Guinea pigs and rabbits are insusceptible.

Etiology

The properties of the virus have not as yet been sufficiently studied. Immunologically, this virus and Mayaro and the Semliki con-

stitute a subgroup in Group A, since these 3 members are more closely related one with another than to others of this group (Casals, 1957, Spence and Thomas, 1958)

Diagnosis

A specific diagnosis can be made only by virus isolation or serologic tests with the patients' sera Care must be taken in interpreting the results of serologic tests, particularly HI, owing to the close relationships existing in the Chikungunya-Mayaro-Semliki viruses complex The clinical differentiation of this disease from dengue rests on the absence of adenitis in Chikungunya as well as frequent association of a rash appearing with or after the secondary fever, absence or mildness of headache, lack of pains postorbitally or with eye movements and characteristic chronicity of joint pains

Treatment

There is no specific treatment, only symptomatic, and opiates are often indicated for alleviation of the arthralgia

Epidemiology

The virus was first isolated from the blood of man and from mosquitoes, bedbugs collected in a patient's hut may have also contained the virus Ross (1956) showed the association between the virus and the disease in the Tanganyika outbreak when in 15 paired sera from patients the samples collected between 5 hours and 4 days after onset had neutralization indices between 0 3 or less and 1 1, but in convalescence, 8 to 16 days after onset, the indices were between 2 1 and 2 3 or higher Spence and Thomas (1958) by HI test demonstrated antibodies in 16 per cent of 25 acute-phase sera, while in a group of 40 convalescent-phase sera, 72 per cent were positive

The epidemic extended from July, 1952, to March, 1953, the majority of cases arose between November and February with most of them seen in January The total number of persons attacked is not known, however, of 2,093 persons living in a number of localities, 860 came down Native Africans, Asians and Europeans were equally involved Persons over 45 years old seemed in some areas to be resistant When the illness attacked one, all the other inmates of a hut developed it; within 2 or 3 weeks, 60 to 80 per cent of a village became sick

In Africa, the clinical disease is believed to be present also in Portuguese East Africa The virus has been isolated from man in Tanganyika, Uganda and Union of South Africa Limited information by means of HI tests indicates that infection with Chikungunya virus may cause either subclinical or milder manifestations than described above, and that this virus, or one very closely allied to it, may be active in other localities Thus (Casals and Theiler, 1956) in the absence of any recorded disease resembling the one in Tanganyika, antibodies against this virus were found in the following areas 11 of 22 residents in Malaya, 10 of 42 in the Union of South Africa, and 35 of 64 in Nigeria

The virus was recovered from two species of mosquitoes trapped in huts *Culex fatigans* and *Aedes aegypti* An additional strain was secured recently from *Aedes africanus* caught in the Zika forest Lumsden (1955) considers *Aedes aegypti* as the vector on epidemiologic grounds Ross (1956) states that the virus could be recovered from mosquitoes fed on patients during their acute illness as late as 33 days after the infected meal Whitman (1956) finds the virus capable of multiplying in the body of *Aedes aegypti* by salivary-gland tissue transfer in series in mosquitoes, since each transfer represents a dilution of 10^{-5} by weight of gland, such a prodigious increase of virus would support its classification as arthropod-borne

There is, at present, no means for prevention except mosquito control or abatement

MAYARO VIRUS DISEASE

Five cases of a mild, febrile malady were observed in 1954 in residents of Trinidad, B W I, from each, a hitherto undescribed virus was isolated by intracerebral inoculation of acute-phase serum into newborn mice The virus was named Mayaro after the district where the first case was observed (Anderson et al, 1957) Shortly afterward, in 1955, an epidemic which may have involved about 50 persons, erupted along the Guama River, Para, Brazil, and from 6 patients additional strains of Mayaro virus were isolated (Causey

ulosum was found to modify experimental infection in the mouse (Shope, 1953)

Within Group A, Semliki virus is more closely allied serologically to Chikungunya and Mayaro viruses than to the other agents of the group Owing to this close serologic relationship, antibodies found in nature either in man or in animals, capable of reacting with Semliki virus, must be interpreted with caution until their specificity is ascertained Antibodies in man capable of neutralizing Semliki virus have been reported in Uganda (Smithburn et al., 1944), Malaya and Borneo (Smithburn, 1954), India (Smithburn et al, 1954), South Africa (Kokernot et al, 1956) and Brazil (Causey and Theiler, 1958). On the basis of HI tests using an antigen developed by Clarke and Theiler (1955), it would appear as though the antibodies found in Brazil can best be explained by the presence of Mayaro virus in that country (Casals and Whitman, 1957) Limited information indicates that, in some cases, human sera from Africa and Malaya having neutralizing antibodies against Semliki virus react by HI test to a considerably higher titer against Chikungunya than against Semliki virus

CHIKUNGUNYA DISEASE

Introduction

Chikungunya is a newly described human disease first noted in 1952-1953 in Tanganyika It takes its native name from its outstanding symptom, *i e*, a state of being "doubled-up" owing to fulminating, severe joint pains that compel this striking posture

History

An outbreak of a denguelike malady arose in the Makonde Plateau, Newala district of southern Tanganyika. A virus was isolated repeatedly by Ross (1956) from patients' blood in the acute phase, also from wild caught mosquitoes The incitant was then shown to be a new member of Group A arbor viruses (Spence and Thomas, 1958). Recently, additional strains have been recovered from the blood of an African mosquito catcher in the Zika forest near Entebbe, Uganda; and from human cases of denguelike disease in the Union of South Africa (Smithburn, 1957)

Clinical Picture

The following account derives from Robinson's (1955) observations on 115 hospitalized patients and on a number of other affected individuals. The incubation period is 3 to 12 days. The onset is sudden with excruciating pains in the joints, the patients being incapacitated within a few minutes or hours from the onset. A rapid rise of temperature to 102° to 105° F. supervenes, and the victim assumes a doubled-up position and becomes immobile, hence, the name of this illness. The pains occur in the limbs and the spine, but headache is usually mild, and no eyeball or postorbital pains, as found in dengue, are noted, although anorexia and constipation occur. After 1 to 6 days of fever, an apyrexial period of 1 to 3 days is followed in most patients by another less intense fever. At this recurrence, or thereafter, a rash is seen in about 80 per cent of individuals, which is maculopapular, pruritic and present on the trunk and on the extensor surfaces of the limbs The malady in this acute stage endures 6 to 10 days, but in several persons apyrexial joint pains recur intermittently over a period up to 4 months, and at times they practically cripple the victim. No second attacks have been known to arise, no deaths have been ascribed to the disease The blood reveals a leukopenia of 4,000 to 5,000 cells No pathologic reports on patients or experimental animals are as yet available

Experimental Infection, Host Range

The virus is pathogenic for suckling mice after intracerebral or intraperitoneal inoculation. The LD_{50} titer by the former route is 10^{-7}, and the incubation period 2 to 5 days. Adult (28-day-old) mice were not as highly susceptible (Ross, 1956) even when the suckling-mouse-adapted strain in its 100th passage was given, but with the 160th passage they developed a lethal infection with only a few survivors, the titer was 10^{-6}, and the incubation period 4 to 8 days, they succumbed after 3 to 5 days. Guinea pigs and rabbits are insusceptible.

Etiology

The properties of the virus have not as yet been sufficiently studied Immunologically, this virus and Mayaro and the Semliki con-

delta, of over 400 persons whose sera were tested, 27 per cent had antibodies, in those under 15 years, the percentage of positives was 14, and in those older than 15 years, 34 In the Union of South Africa (Weinbren et al, 1956), 9 per cent of 160 non-European residents had antibody against the virus

MIDDELBURG VIRUS

From wild caught mosquitoes, *Aedes caballus* and *Aedes* (*Banksinella*) sp, Kokernot et al (1957), isolated at least two strains of a hitherto undescribed agent which was named Middelburg virus from the district in the eastern Cape Province, South Africa, where the agent was recovered They showed that the virus belongs in Group A and is transmissible experimentally by *Aedes caballus* In addition, newborn mice were found to be susceptible to intraperitoneal as well as intracerebral inoculation, adult mice were insusceptible Lambs developed a rapid febrile response (to 106° F) following inoculation of the virus, no other signs of illness were observed, and recovery was the rule In a limited survey, neutralizing antibodies were found in 2 of 9 persons and 10 of 13 ewes Although an epizootic was present in sheep at the time of the isolation of this agent, its connection with the outbreak in sheep was not established

GENERAL COMMENTS ON GROUP A, ARBOR VIRUSES

Certain practical usages and theoretical considerations regarding the classification here presented are in order

On the basis of serologic reactions, including NT, HI and CF tests, with experimental animal sera, it is possible to show that in Group A there exist 2 subgroups or complexes characterized by the fact that the viruses in each subgroup are more closely related to one another than to the remaining agents in Group A These subgroups are (1) Chikungunya, Mayaro and Semliki Forest viruses and (2) WEE and Sindbis

The serologic overlaps shown in the Chikungunya-Mayaro-Semliki complex are apt to be quite marked and can present difficult diagnostic problems, mention has been made earlier in this chapter of the revised interpretation placed on the detection of neutralizing antibody against Semliki Forest virus in the Amazon Valley In such instances, it is advisable to test the sera under investigation against all 3 agents; or, if the diagnostic problem involves a virus isolate, to test the virus against the 3 immune sera; the nature or pattern of the serologic results is of definite help. Further, the study of the characteristics of the virus, of the clinical, ecologic and epidemiologic pictures can be of additional aid in resolving overlapping reactions

The WEE-Sindbis relationship, as observed with experimental animal sera by HI and CF tests, is characterized by a strong overlap given by Sindbis serum against WEE antigen, the converse reaction, on the other hand, is usually more moderate.

The equine viruses (WEE, EEE, VEE) are agents which, serologically, are different from each other But one of the essential points of similarity among the 3 is that ordinarily the encephalitis in man is unusual or accidental, the usual form of infection being, at least with WEE and VEE (less is known about EEE), asymptomatic, abortive, or systemic Indeed, VEE is almost always a systemic disorder, often resembling the clinical picture of influenza or dengue, although the horse may show encephalitis For WEE and EEE, the order of susceptibility is probably first woodland animals (especially birds), then horses and last human beings

Finally, antibody surveys for Group A arbor viruses, made under conditions favorable for proper interpretations despite cross-reactions, reveal that large numbers of the general population in endemic and epidemic areas develop clinically inapparent infections Even with the virus of EEE with which, in the earlier surveys, there was little evidence of subclinical infection, there seem to be an increasing number of reports of persons that have antibody in the absence of recognizable encephalitis

(For complete references, see also second edition, chapter 11)

Anderson, C R, Downs, W G, Wattley, G H, Ahin, N W, and Reese, A A, 1957, Mayaro virus a new human disease agent II, Isolation from blood of patients in Trinidad, B W I, Am J Trop Med 6, 1012-1016

and Maroja, 1957) A strain of virus identical with or closely related to Mayaro was isolated from man in Bolivia (Buescher, 1955) and was called Uruma virus Antibodies against Mayaro virus have been detected in residents of Colombia (Sanmartin-Barberi, 1956).

The disease as seen in the two areas mentioned was characterized by moderate fever, 100° to 103.5° F, severe frontal headache, occasionally by epigastric pain, backache, nausea, vertigo and mild jaundice; the symptoms lasted from 2 to 6 days

The available strains of the virus are pathogenic for newborn mice, with LD_{50} at about 10^{-7} after intracerebral or intraperitoneal exposure; adult mice do not show visible signs of infection After intracerebral inoculation of some strains of this virus guinea pigs occasionally respond with neurologic signs followed by death

Casals and Whitman (1957) showed by serologic tests that Mayaro virus, in addition to being an arbor Group A agent, is closely related to Semliki Forest virus Further, both Mayaro and Semliki viruses are serologically more closely related to Chikungunya virus than to the remaining agents in Group A, as a consequence (Casals, 1957), the three agents are considered as a serologic subgroup or complex within Group A These close serologic relationships must be borne in mind when interpreting the results of immunologic reactions thus, Causey and Maroja (1957) express the view that neutralizing antibodies against Semliki virus found in 9 6 per cent of 551 persons in the Amazon Valley may be due to infection with Mayaro rather than Semliki virus

SINDBIS VIRUS

Sindbis virus is so named from the Sindbis district in the Nile delta where it was first isolated in 1952 by Taylor (Taylor et al, 1955); several isolations followed from culicine mosquitoes and one from the blood of a hooded crow. The virus was recovered in India in 1953 (Shah et al, 1957) from mosquitoes, mites and birds Early in 1954, an epizootic broke out in cattle, accompanied by an epidemic of a febrile disorder arising from a cause still unknown near Johannesburg, Union of South Africa. From the mosquitoes of the neighborhood, three strains of virus identical with or closely related to the Egyptian Sindbis virus were recovered (Weinbren et al, 1956) The effects of the virus on man are unknown, since as yet no disease has been associated with this agent, nor has the virus been isolated from man

On isolation, the strains of virus available were pathogenic for newborn mice, not for adults Most strains have remained thus; but at least one strain has been adapted to adult mice by serial intracerebral passage (Weinbren et al, 1956) In 1- or 2-day-old mice, the virus produces paralysis and death in 2 to 6 days after intracerebral or peripheral inoculation, with LD_{50} at about 10^{-7} by the former route and slightly lower by the latter Rabbits react to intracerebral inoculation of the virus with no apparent ill effects In birds, including chicks, and certain monkeys, exposure to the virus sets up a viremia only, without apparent illness. cavebats and hamsters come down with signs after inoculation by several routes (Reagan et al, 1956). The histopathologic picture in affected mice reveals foci of separation, fragmentation and loss of striation of myofibrils along with nuclear degeneration—a Coxsackie viruslike lesion. In the CNS, however, the encephalitis is of a type *sui generis* and shows chiefly neuronal degeneration and necrosis without edema or perivascular infiltration The virus is highly pathogenic for chick embryos which die within 72 hours; in chick-embryo tissue cultures occurs a marked cytopathogenesis of the fibroblastic outgrowths (Frothingham, 1955) By gradocol-membrane filtration, the virus has a particle size between 40 and 48 mμ (Taylor et al, 1955). Within Group A, Sindbis virus has been found to be more closely related serologically with WEE than with the remaining viruses in the group (Casals, 1957).

Experimentally, the virus was easily maintained in several species of *Culex* mosquitoes and transmitted by bite to newborn mice; a tick, *Ornithodoros savignyi*, could be infected by parenteral puncture and was capable, subsequently, of transmitting the infection by feeding upon infant mice.

Antibody surveys by means of NT test suggest a wide vertebrate host range including man, domestic quadrupeds, birds and domestic fowl (Taylor et al, 1955) In the Nile

Arthropod-Borne Group B Virus Infections of Man

The group classification of the arbor viruses is based on antigenic relationship (cf Chap 12), the members of Group B are listed in Table 12 The viruses are subgrouped, in so far as present knowledge permits, according to the closeness of the antigenic relationship existing between the members, although it should be kept in mind that cross-reactions of varying degrees can be demonstrated between all members of the group.

This chapter deals with all of the above viruses except dengue and yellow fever, which are the subjects of Chapters 15 and 16

On the basis of the rather marked antigenic relationship between the viruses of Group B, it is believed probable that all the members stemmed originally from one parent virus and that the individual members represent mutants with somewhat different antigenic and pathogenic properties selected by the pressures of the various host environments to which they have been exposed in the course of their evolution There are many examples, from the laboratory, which illustrate the possibility of selection, by environmental manipulation, of strains of these viruses with modified pathogenic properties The best-known examples are perhaps the adaptation of pantropic yellow fever virus to the brain of the mouse with concomitant loss in viscerotropism for man and the even more successful production, in tissue culture, of the 17D vaccine strain of yellow fever which is almost totally devoid of all pathogenic potentiality for man

TABLE 12 SUBGROUPS GROUP B, ARBOR VIRUSES

circumstance of an outbreak with multiple cases, diagnosis of the nature of the epidemic may be obtained by virus isolation from a few cases or by uncomplicated serologic response in a sufficient number to permit presumptive diagnoses of those having the more complex serologic responses It must be borne in mind that new members of the arbor family continue to be isolated and that the presence of Group B antibodies may be attributable to a new agent

In Chapter 12, the epidemiologic implications of the immunologic relationships between the members of Group B are discussed It is believed possible that the presence of one or more members of the group in a given geographic area may, through the production of cross-immunity, act to modify the disease picture caused by or limit the spread of other related viruses It is of interest that members of the closely related subcomplex of St Louis, Japanese B, Murray Valley, West Nile usually seem to occur in a given geographic region in the absence of other members of the complex, St Louis is found in the western hemisphere, Japanese B in the Far East, Murray Valley in Australia and New Guinea, and West Nile in Africa and the Middle East India provides an exception to this rule in that both West Nile and Japanese B have been proved to coexist in one localized area As one application of knowledge of the group relationships, advantage is being taken of the broad spectrum of neutralizing antibodies produced by exposure to more than one member of Group B in an attempt to develop more effective vaccines For references to experimental work bearing on these points, the reader is referred to Chapter 12

ST LOUIS ENCEPHALITIS

(Synonyms American encephalitis used by Japanese and Europeans, SLE as abbreviation)

Introduction

Infection with the virus of St. Louis encephalitis is widespread in central and western United States and produces a varied symptomatology prevailing in the summer and early fall. The disease is similar in many respects to that caused by western equine encephalitis virus and Japanese B encephalitis virus.

History

In the summer of 1932, an epidemic of encephalitis, which was first regarded as von Economo's disease, occurred in Paris, Ill During the following summer, a similar epidemic occurred in and around St Louis and Kansas City, Mo , 1,130 cases were reported in St. Louis County. The disease was then believed to be a nosologic entity different from von Economo's encephalitis. Muckenfuss et al. recovered the causal virus in 1933 by inoculation of infected human brain tissue into monkeys, and in the same year, Webster and Fite obtained similar results by using albino mice as experimental hosts The disease recurred in St Louis County in 1937, in epidemic form involving several hundred persons and since that time has been recognized over a wide area of the United States In some years, only small outbreaks or sporadic cases have occurred, but the disease has been a recurrent problem in certain of the far western states, the last sharp outbreak in California was in 1954 with 99 proved cases (Longshore, 1955). Also, in 1954, one of the largest recorded epidemics of the disease occurred in the lower Rio Grande valley of Texas. There were 373 reported cases, but it is estimated that the actual total was over 1,000 (Chin et al , 1957) Other fairly extensive recent outbreaks have occurred in the lower Ohio River valley in 1955, and in west Texas, in the Grand Junction area of Colorado and in Louisville, Ky , in 1956

Clinical Picture

The description is taken from reports of recent outbreaks of the disease as it occurs today (Lennette and Longshore, 1951; Kokernot et al , 1953; Kunin and Chin, 1957; Ranzenhofer et al , 1957). The clinical description of the early epidemics can be found in previous editions of this volume.

Most cases have a relatively benign course consisting of a brief febrile illness with severe headache, the illness lasting for a few days and being followed by complete and uneventful recovery. In a small percentage of patients, a more progressive illness occurs The onset is characteristically abrupt, with high fever, very severe generalized or localized

The viruses of Group B are capable of causing a variety of disease pictures However, as discussed in Chapter 12, there are certain similarities which are common to all Man is usually an incidental or even tangential (dead-end) host, and the most common result of his infection is the production of a clinically silent or inapparent infection detectable only by the subsequent development of specific antibodies. Certain of the viruses produce their clinical manifestations as a part of a generalized systemic infection Examples are dengue and West Nile fever with their characteristic clinical picture of fever, malaise, rash and lymphadenopathy Other members of the group, in addition to causing inapparent or mild systemic infections, apparently have acquired certain tissue tropisms with the result that, upon occasion, they may involve and damage a specific tissue or organ such as the liver or the brain Yellow fever, St Louis encephalitis and Japanese B encephalitis serve as examples of this type

From the foregoing, it can be realized that the outcome of infection with one of these agents, apart from often being symptom-free, is unpredictable in terms of the severity of the clinical result Even more striking is the fact that the same virus can cause markedly diverse clinical pictures For example, a neuroadapted strain of yellow fever employed as a vaccine has been found to cause a significant incidence of encephalitis rather than liver damage in human recipients (MacNamara, 1953a). West Nile virus, which is usually associated with a denguelike disease picture, produced several cases of encephalitis when given in large doses to humans with advanced malignant neoplasia (Southam and Moore, 1954a) The most diverse array of disease entities has been found to be caused by various strains of the Russian tick-borne encephalitis complex. Although antigenic variation exists between the members of this complex, some investigators feel that all should be considered as strains of one viral entity. Yet, the clinical pictures resulting from infection with one of these strains may be, a fairly mild biphasic febrile reaction with or without meningeal irritation; a severe encephalitis resulting in death or permanent disability; an acute hemorrhagic picture of greater or lesser severity but with no suggestion of CNS involvement (see below).

It should be apparent from the foregoing that the clinical diagnosis of infection with one of the arbor B viruses may be a difficult, if not impossible, task since different viruses may cause the same clinical picture and the same virus may cause different clinical pictures. This, then, becomes a problem which can be resolved only with the aid of the diagnostic laboratory, and even there the problem is not always easy

As a general rule, the most rapid and definitive method of diagnosis is by virus isolation However, this is often impossible or impractical. Therefore, most diagnoses must rest upon serologic evidence. The details of the technics used for serologic diagnosis are given in Chapter 10, and a discussion of the general applications and results is presented in Chapter 12 In the latter chapter, it is stressed that the diagnosis of a Group B infection is frequently complicated by the degree of immunologic cross-reactivity which exists between members of the group The ease and the accuracy with which a serologic diagnosis can be made depends upon the geographic area in which the infection is contracted In the United States, for example, St Louis virus is the only member of the group now known to

(NT) can be used In areas where more than one member of the group infect man, the problem may be more difficult Here, the HI test may give a relatively specific answer or it may reveal only that a Group B infection has occurred, resulting in broadly cross-reactive HI antibodies Depending on the viruses involved, either the CF or the quantitative intracerebral NT may be the diagnostic procedure of choice In regions of high Group B endemicity, where individuals may have had experience with other members of the group prior to the present infection, diagnosis may become quite complex due to the broad serologic response engendered by infection with two related Group B agents If the case is an isolated one, in the absence of virus isolation, diagnosis may prove to be extremely difficult or even impossible. In the more usual

up to 10^{-5} intranasally. Suckling mice are much more susceptible to peripheral inoculation of the virus than are adults This is the basis for the most sensitive type of neutralization test first devised by Olitsky and Harford, 1938, and subsequently applied to St Louis and other viruses by Lennette and Koprowski (1944).

Rats (7 to 8 days old) and wild mice (gray house mice) develop a lethal encephalitis following intracerebral inoculation of the virus. Hamsters, horses and rhesus monkeys are susceptible to intracerebral inoculation with some but not with all strains The rhesus monkey responds by developing fever and signs of CNS involvement but usually recovers and is an unsatisfactory animal for serial propagation of the virus. Cebus monkeys are insusceptible, as are adult rats, sheep, kittens and ferrets

Various animals such as guinea pigs and rabbits develop inapparent infections after inoculation by any route as do monkeys, horses and adult mice after subcutaneous injection with small doses of virus Use is made of this type of reaction in the production of specific immune serum Chickens, ducks and several species of wild birds have been shown to respond to peripheral inoculation of small doses of virus by the development of asymptomatic infections characterized by some degree of viremia The fact that animals in apparent health can harbor virus in the blood which, in turn, may infect insect vectors is considered of prime epidemiologic importance (Hammon et al, 1951a, Chamberlain et al, 1957)

The virus multiplies in the chick embryo after infection by the yolk-sac or the chorioallantoic routes The most commonly used procedure is that of inoculating the chorioallantoic membrane of a 10- to 12-day-old chick embryo. After incubation at 37° C for 3 to 4 days or longer, the egg is opened The membrane is edematous and opaque and exhibits a diffuse proliferation of the ectodermal layers and focal necrosis The virus does not produce definite, discrete pocks or localized lesions but is recoverable from the membrane, the brain and the various viscera and, by the intracerebral mouse test, usually has a titer of 10^{-2} to 10^{-3} As a rule, chick embryos are killed by the virus without specific pathologic changes

A number of investigators have shown that the virus can be propagated in suspended cell cultures of chick or mouse embryo tissue, although cytopathic changes are not observed The virus can multiply in, and in some cases adversely affect, certain types of neoplastic cells. This has been shown both in vivo (Sharpless et al, 1950, Koprowski and Norton, 1950, Koprowska and Koprowski, 1953) and in vitro (Pollard and Bussell, 1952; Scherer and Syverton, 1954). The results of Pollard and Bussell indicate the types of cells which might be useful in tissue culture studies with this virus

Etiology

The basis for placing the virus in Group B of the arbor viruses is an immunologic one as discussed in Chapter 12 It also forms part of a subgroup, the members of which are listed in the introduction to this chapter The diameter of the virus as determined by gradocol membrane filtration is 20 to 30 mμ It passes readily through Berkefeld V and N and Seitz filters. It deteriorates on standing at room temperature, especially at high dilution. This effect can be retarded by the use of a protein diluent such as 10 per cent normal serum or 0.75 per cent buffered bovine plasma albumin It is best preserved by being kept frozen at about −70° C or in buffered 50 per cent glycerol at 4° C or in the lyophilized state In preparing the virus for lyophilization or storage as a frozen suspension, it is best to use undiluted or 50 per cent heated normal serum or a serum fraction such as bovine plasma albumin The virus is susceptible to the action of desoxycholate (cf. Chap 12) and to ethyl ether (Sulkin and Zarafonetis, 1947) which serve to distinguish it from certain other, nonarbor, viruses It is inactivated by 0 1 per cent formalin in from 12 to 18 hours at room temperature (7 to 9 days at 5° C) but not by 1 per cent phenol within at least 25 days Filtered virus is inactivated when held at 56° C for 30 minutes The infective principle is more stable on the alkaline than the acid side of neutrality

Chanock and Sabin (1953) first demonstrated a viral hemagglutinin, most active for erythrocytes of the 1-day-old chick, in infected mouse-brain suspensions The hemagglutinating principle is especially sensitive to pH change but it quite stable at about pH 9

(occipital) headache, malaise, stiff neck and chilly sensations or chills. Nausea and vomiting not infrequently occur In young children, restlessness and irritability are prominent, while in adults, drowsiness, lethargy and some degree of disorientation are common. Convulsions are more common in young children, but they can occur in seriously ill older patients In general, the occurrence of convulsions is a poor prognostic sign, indicating pronounced neurologic damage and greater probability of sequelae Other commonly observed signs and symptoms are tremors, speech difficulties, muscle pains, muscle weaknesses, photophobia and visual disturbances Meningeal irritation is frequently found, as evidenced by nuchal rigidity and positive Kernig and Brudzinski signs In severe cases, stupor, coma or delirium may supervene and may persist for some time One striking observation has been the dramatic suddenness with which remissions can occur leading to complete recovery of patients critically ill at first observation In such cases, recovery is complete within a relatively short time except for generalized weakness and fatigue, which may serve to prolong convalescence. Fever usually lasts from 3 to 10 days, declining gradually In the seriously ill older patient, the illness may be more prolonged with a low-grade fever persisting for 2 to 3 weeks, while in younger patients the febrile phase reaches a higher peak but has a shorter course Although convalescence may be prolonged and marked by generalized weakness, tremors and dulling of intellectual functions, the prognosis for complete recovery is generally good Permanent sequelae, which are uncommon, consist of personality changes, mental deterioration, muscle weakness or frank paralysis. Parkinsonism has not been seen

The white blood count may show either leukopenia or mild leukocytosis, the latter being more common The spinal fluid is under slight pressure and is clear with a pleocytosis of 50 to 250 cells, which are predominantly polymorphonuclear in the early stages and mononuclear later. In young children, the cell count is usually higher and may exceed 500 There is no correlation between clinical severity and height of cell count. Spinal fluid protein is slightly increased, and sugar is normal.

Pathologic Picture

Gross examination of the brain and the cord reveals edema, vascular congestion and small hemorrhages. Microscopic examination shows a cellular infiltration, chiefly of lymphocytes, and engorgement of blood vessels in the meningeal layers. In other tissues of the CNS, there are evidences of acute inflammation, small hemorrhages, focal glial proliferation, and diffuse infiltration of lymphocytes, polymorphonuclear leukocytes, and plasma cells; lymphocytes predominate. The outstanding lesions are the degeneration and necrosis of neurons associated with neuronophagia, exceptionally, small sterile abscesses and areas of necrosis of the gray and white matter occur. Perivascular edema with loculation of the adjoining parenchyma may occur. Perivascular demyelination is not seen

According to Wolf (1950), the relative rarity of permanent neurologic sequelae can be accounted for by the fact that focal necrosis of the tissue is seen far less commonly in St Louis encephalitis than in eastern and western equine and Japanese B encephalitides. However, in areas where western equine and St Louis infections coexist, it has been found impossible to distinguish, in the individual case, between the lesions caused by the two (Finley and Hollister, 1951)

Experimental Infection; Host Range

The experimental animal of choice is the laboratory white mouse It is with this species that Webster in 1937 developed a strain particularly susceptible to St Louis, louping-ill and Russian tick-borne viruses. The strain was designated albino Swiss-W mouse by Casals and Schneider, 1943 Mice can be infected regularly by the intracerebral route, which is the method of choice, although they can also be infected by the intranasal route and occasionally by feeding them virus suspensions, Harford and Bronfenbrenner, 1942 After intracerebral or intranasal infection, an incubation period of from 3 to 4 days is followed by ataxia, ruffled fur, convulsions and paralysis. Prostration and death occur from 1 to 5 days later, and the pathologic picture resembles that seen in the human disease Mice develop the experimental disease when dilutions up to 10^{-7} or 10^{-8} of mouse-adapted virus are given intracerebrally or

nosis of the infection in the United States has not been thought to be complicated by the possibility of infection with related viruses giving serologic cross-reactivity However, it must be kept in mind that an individual may have resided in parts of the world where other Group B virus infections occur. In addition, the recent report of the isolation in Texas of a virus serologically related to St Louis from the salivary glands of insectivorous bats (Burns et al, 1957) raises the question of the possibility of human infections with this agent The evidence available concerning the agent is presented elsewhere in this chapter. Where the possibility of infection, past or present, with a related virus cannot be excluded, diagnosis may be more difficult (cf *Introduction to this chapter and Chap 12*). In such cases, several related viruses or antigens and more than one type of test should be used

Treatment

There is no specific treatment. Symptomatic treatment is indicated, although the severe headache is not relieved by analgesic or even narcotic drugs Good nursing care and general supportive treatment are extremely important for the severely ill patient

Epidemiology

As has been stated earlier, this virus most commonly produces a clinically inapparent infection in man This has been recognized since Wooley and Armstrong (1934) demonstrated NT antibody in 36 per cent of normal individuals following the 1933 epidemic in St Louis. Since that time, a number of studies have shown inapparent infection rates ranging from 10 to 70 per cent of individuals in an endemic or epidemic area (Muckenfuss et al, 1938, Reeves et al, 1952, Ranzenhofer et al, 1957, Chin et al, 1957)

The seasonal incidence of the disease is definite, most cases occur in the late summer and early fall The disease occurs over a wide area of the United States from Kentucky to the Pacific coast in the form of sporadic cases, small outbreaks or rather extensive epidemics It is variable in its appearance from year to year in any one area, but studies of recent epidemics have always revealed the presence of conditions especially or unusually favorable to mosquito breeding (Stead and Peters, 1953, Chin et al, 1957; Ranzenhofer et al, 1957). Distribution of the infection tends to be rural or suburban rather than urban

A recent survey of residents of Trinidad, B.W I., for the presence of NT antibody against various arbor viruses demonstrated its presence against St Louis virus in 4.3 per cent (Downs et al, 1956b). This suggestive evidence for the presence of a heretofore unrecognized virus in that area has been amply confirmed by the isolation of the virus both from mosquitoes (Anderson et al, 1957) and from a nestling wild bird (Downs et al, 1957)

The age distribution of clinical cases has varied in different epidemics In the 1933 epidemic and in the recent ones in Texas and Kentucky, the highest incidence was in persons over 45 years. Longshore et al (1956) state that in California, St Louis virus infection shows no apparent age selection except that it is rare in infants under one year There seems to be no consistent difference related to sex The mortality rate is difficult to assess, since many mild cases escape diagnosis but the case fatality rate appears to have been much lower in recent outbreaks than the 20 per cent figure given for the original epidemic in St Louis (Chin et al., 1957).

The chief vector of the disease in the Far West appears almost certainly to be *Culex tarsalis* (Hammon et al, 1951a; Stead and Peters, 1953) However, the vectors incriminated in the recent Texas and Kentucky outbreaks were *Culex quinquefasciatus* and *Culex pipiens*, respectively (Chin et al., 1957; Beadle et al, 1957, Ranzenhofer et al, 1957) In both cases, the mosquito incriminated was that of the prevalent species, and virus was isolated from naturally infected mosquitoes in pools In the United States, the virus has been isolated from 2 additional species of naturally infected mosquitoes, *Culex stigmatosoma* and *Aëdes dorsalis*, besides the 3 already mentioned (Reeves, 1953). The 3 species from which the virus was isolated in Trinidad were *Culex coronator*, *Culex caudelli* and *Psorophora ferox* (Anderson et al., 1957) In the laboratory, transmission of the virus to animals has been effected by 12 species of mosquitoes from 3 genera: *Culex, Aëdes* and *Culiseta* (Hammon and Reeves, 1943). It seems apparent that the chief mosquito vector varies in different localities, al-

where it maintains its titer on dilution in the absence of added protein (Clarke and Casals, 1955). Inhibitors of the hemagglutinin, which are probably lipid or lipoprotein in nature, occur in serum and in tissue homogenates. Unlike the infective principle, the hemagglutinin is not inactivated by actone or ether, which forms the basis for the preparation of an excellent antigen (Casals and Brown, 1954) Neither the infective nor the hemagglutinating activities are precipitated by protamine sulfate, and a considerable degree of preliminary purification can be achieved by the treatment of virus suspensions with this substance A good hemagglutinating antigen results from such treatment of alkaline suspensions of suckling mouse brain (Warren et al, 1949, Clarke, unpublished results). The relationship of the hemagglutinin to the infective particle is not clear at present

Hemagglutination-inhibiting, neutralizing and complement-fixing antibodies appear in the blood of humans and animals infected with the virus or in animals following vaccination with inactivated virus In general, NT and HI antibodies appear earlier and last longer than do CF antibodies. This difference is important in demonstrating a diagnostic rise in specific antibodies and also in indicating whether detectable antibodies are due to a recent infection or one acquired in the past NT antibody persists for many years if not for life The duration of HI antibody has not yet been determined accurately

The transplacental transmission of NT antibody has been demonstrated in mammals and the transovarian in birds (Smith, 1943, Reeves et al., 1954) The latter observation is believed to be of particular importance due to the significance of birds in the epidemiology of the disease.

Diagnosis

The clinical pictures seen in infections with St. Louis virus are not sufficiently characteristic to permit unassisted diagnosis The mild infections resemble many febrile diseases, and those infections involving the CNS are similar to or identical with CNS infections by a variety of agents. The seasonal incidence is useful in suggesting the possibility of St. Louis infection but is of no value in excluding the two infections most commonly confused with St Louis encephalitis, namely, western equine encephalitis and nonparalytic poliomyelitis A specific diagnosis can be made only by virus isolation or serologic tests

Virus isolation is of little practical value for human diagnosis except in certain fatal cases. The virus has never been recovered from spinal fluid of humans and only very rarely from blood From patients dying early in the disease, it is possible to isolate the virus from CNS tissue. This is best done by inoculation of tissue suspensions intracerebrally into adult or, preferably, suckling mice The brains of animals which sicken or die can then be used for virus identification This is accomplished by use of the same types of procedures as are employed for serologic diagnosis, except that in this case the virus or the antigen constitutes the unknown and is tested against various standard immune sera The details of the procedures used are given in Chapter 10, and a general discussion of their applications to arbor virus infections and Group B virus infections appears in Chapter 12 and in the introduction to this chapter

Accurate diagnosis usually rests on the demonstration of a rise in specific antibodies. For this purpose, two blood specimens are required, the first taken as early as possible in the acute phase, and the second during convalescence, usually about 3 weeks after onset The demonstration of specific antibodies

acquired as the result of the illness rather than an earlier infection Although any of the 3 types of tests (HI, CF or NT) can be used, the CF test has had the most extensive use and is probably the procedure of choice in the United States It is simpler, quicker and less expensive than the NT, and since CF antibody develops more slowly, the acute phase specimen is more likely to be negative or at most to show a low titer of antibody, permitting the demonstration of a clearcut rise in the second, later specimen Finally, since CF antibody does not persist for as long as NT and HI antibodies, results are less likely to be complicated as a consequence of past infection The HI test offers many of the advantages of the CF test except that the antibody develops more rapidly and is more persistent. As has been stated in the introduction, diag-

spread occurrence of the infection throughout the Far East has been recognized only rather recently, mainly by the demonstration of a significant incidence of antibodies in the human and animal population and occasionally by the occurrence of clinical cases

Hayashi, 1934, transmitted the disease to monkeys by the intracerebral inoculation of brain tissue from fatal cases In 1935, a number of other Japanese investigators, including Kasahara, Kawamura and Taniguchi and their associates, isolated the virus from fatal cases and demonstrated neutralizing antibody in recovered cases by using mice as experimental animals

Clinical Picture

The description is based on recent reports of a large number of confirmed cases seen both in the local inhabitants and in American military personnel in epidemic areas (Lewis et al, 1947, Sabin, 1947, Hullinghorst et al, 1951, Dickerson et al, 1952, Lincoln and Sivertson, 1952, Shapoval et al, 1954) Mild or abortive cases have been recognized in which the chief manifestations consist of headache, low-grade fever and malaise of a few days' duration, their incidence is impossible to assess Frank encephalitic manifestations may develop gradually following an initial picture similar to that of the abortive case, or the onset may be abrupt with severe headache and fever rapidly developing into a disabling illness Lincoln and Sivertson (1952) consider nuchal rigidity, headache, fever and sensorial change to be a helpful diagnostic quadriad, others stress the lethargic affect, masklike facies and slow, thick speech, or other speech disturbances Chills and high fever are common in adults, but, although fever is high, chills are said to be uncommon in children Convulsions are common in children but rare in adults Marked flushing of the face, generalized aches and severe anorexia are characteristically seen, and other gastrointestinal disturbances are not uncommon Sensorial change varies from confusion to delirium or coma in severe cases Tremors, including ocular and extraocular motor disturbances, frequently occur Facial paralysis or paralysis of one or more extremity is more common in children, whereas adults most often develop a relatively symmetrical paresis without paralysis or corresponding sensory changes Carpopedal spasm, muscular rigidity or generalized spasticity are found, especially in the more seriously ill patient Abnormal deep and superficial reflexes are frequently observed but are quite variable The fever is sustained, with a relative bradycardia, and reaches its peak in from 2 to 4 days, after which it subsides gradually It is unaffected by antipyretics

The return to an afebrile condition is often followed by dramatic improvement, although the duration of the illness is extremely variable Convalescence is frequently rather prolonged, with persistent generalized weakness, lethargy, in-co-ordination, tremors and nervousness Weight loss may be marked, even in those receiving good hospital care Serious sequelae occur in a significant proportion of cases, but even in such patients the prognosis should be guarded, since slow improvement is possible over a prolonged period The most commonly seen sequelae are mental impairment and personality change Second to these is motor impairment, either of the upper or the lower motorneuron type, resulting in paralyses of greater or lesser extent Less commonly observed are aphasia, cerebellar syndromes, organic psychoses and decerebrate rigidity Japanese B encephalitis is, in general, a more serious disease than St Louis encephalitis with a more protracted course, slower convalescence, a higher incidence of [illegible]
32,000, although the average is around 14,000 There is a moderate neutrophilia and shift to the left The count falls rapidly and returns to normal in the first or second week. The cerebrospinal fluid is usually clear, with normal or slightly elevated pressure and a pleocytosis of 10 to 400 cells, mainly mononuclear Occasionally over 1,000 cells are found, but the degree of pleocytosis is unrelated to the severity of the disease The protein is moderately elevated and remains so for some time as does the pleocytosis, the amount of sugar is normal

Pathologic Picture

Macroscopically, the brain and coverings show edema and congestion, especially in the

though *Culex tarsalis* is particularly efficient owing to the low level of viremia necessary for infection and the fact that it frequently feeds on both avian species and human beings (Reeves, 1953) The role of mites as vectors is at present problematical. The situation as discussed by Reeves and his associates (1955) is as follows Smith et al, 1944, reported the isolation of St Louis virus from chicken mites in nature and, subsequently, the experimental transmission and transovarial passage of the virus by the same mite, other investigators succeeded in isolating the virus from mites parasitic on domestic and wild birds, however, recent extensive field and laboratory studies have failed to furnish convincing evidence for the importance of mites in the epidemiology With the American dog tick, *Dermacentor variabilis*, transovarial passage of the virus through two complete generations has been demonstrated (Blattner and Heys, 1944).

The long-term reservoir of the virus remains unknown, but the role of domestic fowl and wild birds as important sources of vector infection and spread of the virus has been amply indicated by the work of Hammon and Reeves and their associates (Hammon et al., 1951a, Reeves, 1951) who believe that mammals (including man) are not important reservoirs or sources of infection The virus has been isolated from naturally infected wild birds in the United States on 3 occasions and on 1 occasion each in Haiti and Trinidad (Ranzenhofer et al, 1957, Chamberlain et al., 1957, Downs et al, 1957) Studies on the experimental infection of domestic fowl and wild birds have been mentioned previously.

Control

Immunization by means of a formalin-inactivated vaccine was shown to be capable of inducing a high degree of immunity to challenge in mice and to produce detectable neu-
an
a
il-
able and would be impractical for general use because of the cost, the temporary nature of the immunity and the time factor in the face of an epidemic (Reeves, 1951) Since control of the avian sources of vector infection is impossible, control of the vector becomes the only logical approach. As pointed out by Reeves (1951), vector control is practical only if it is economically feasible and is most effective if a thorough knowledge of the principal vector or vectors is available

JAPANESE B ENCEPHALITIS

(Synonyms: Russian autumnal encephalitis, Japanese encephalitis or summer encephalitis; JB, JBE or JE)

Introduction

Japanese B virus infection occurs in a broad band involving all of eastern Asia as far north as the maritime district of Siberia and south well into the East Indies. The band includes the islands off the coast of Asia—Japan, Okinawa, Formosa, Guam, the Philippine Islands and Borneo—and extends westward at least as far as southeastern India (Pond and Smadel, 1954) The disease shows a markedly warm weather seasonal incidence in temperate climates, as in Japan, China and Okinawa, but is not seasonal in warmer regions, such as Malaya It has many features in common with St. Louis and western equine virus infections, including the production of a high proportion of clinically inapparent infections and of a variable clinical picture although, when fully manifest, the CNS involvement in Japanese B encephalitis tends to be the most severe At one time Russian autumnal encephalitis was regarded as a distinct nosologic entity, but later it was shown to be Japanese B encephalitis, Casals, 1944

History

The history of a disease in Japan resembling Japanese B encephalitis goes back at least to 1871, and it has been recognized there as a distinct clinical entity since 1924 when an epidemic occurred involving more than 6,000 cases with an extremely high case fatality rate Since that time epidemics have recurred annually in Japan, although the incidence has varied widely from a small number to over 8,000 cases per year. Epidemics have been recognized in recent years in China, Okinawa and Korea Similar recurrent outbreaks of a seasonal encephalitis have been reported from Formosa, Manchuria and the maritime district of Siberia, but the wide-

mately the same degree of precision Most embryo deaths occur between 48 and 96 hours after inoculation, the virus is found throughout the egg but chiefly in the embryo

The virus can multiply in and in some cases adversely affect certain types of tumor cells in vivo (Sharpless et al, 1950, Koprowski and Norton, 1950, Koprowska and Koprowski, 1953) Haagen and Crodel, 1938, and Kawakita, 1939, showed that the virus could be propagated successfully in Maitland-type tissue culture of chick-embryo cells, and it has been reported to multiply but to produce no consistent cytopathic effect in cultures of chick-embryo fibroblasts, HeLa cells and monkey-kidney epithelium (Scherer and Syverton, 1954, McCollum and Foley, 1957). However, Bhatt and Work (1957) found the virus to produce consistent cytopathic changes after adaptation to both chick-embryo and monkey-kidney epithelial cells McCollum and Foley (1957) report consistent cytopathogenicity for the Detroit-6 cell line in tissue culture without adaptation

Etiology

The immunologic basis for placing the virus in Group B of the arbor viruses is discussed in Chapter 12, the introduction to this chapter lists the other members of the subgroup closely related to Japanese B virus The diameter of the virus has been reported to be 15 to 30 mμ as determined by ultrafiltration through gradocol membranes (Yaoi et al, 1939) The virus passes through Seitz and Berkefeld V and N filters The virus is best preserved by storage frozen at about −70° C, or in buffered 50 per cent glycerol at 4° C, or by lyophilization Satisfactory diluents for preparing the virus for lyophilization or storage as a frozen suspension are undiluted or 50 per cent normal serum, a buffered solution of bovine plasma albumin, or undiluted skim milk adjusted to pH 8 4 Virus dilutions for experimental procedures are best made in 10 per cent normal serum, 0 75 per cent buffered bovine albumin, or 10 per cent skim milk in saline solution The virus is susceptible to the action of desoxycholate (cf Chap 12), which serves to distinguish it from certain other, nonarbor, viruses It is inactivated by 0 2 per cent formalin in the cold without destruction of its antigenicity (Sabin et al, 1943). Filtered virus is inactivated at 56° C. within 30 minutes The infective principle is stable at a somewhat alkaline pH

Sabin and Buescher (1950) reported the occurrence of a hemagglutinin in infected mouse brain suspensions which was demonstrated most satisfactorily with the red blood cells of the 1-day-old chick. The hemagglutinin has the same general properties as does the St Louis viral hemagglutinin (see above) including stability at pH 9 0, resistance to acetone and ether, and the fact that neither the hemagglutinating nor infective activities are precipitated by protamine sulfate

Neutralizing (NT), hemagglutination-inhibiting (HI) and complement-fixing (CF) antibodies develop after infection It has been the experience of American investigators that NT and HI antibodies develop rather rapidly and are usually demonstrable within the first week, while in most cases the CF antibody rises more slowly (Sabin, 1947, Tigertt and Hammon, 1950, Southam, 1956) Soviet investigators, in contrast, report that with their technics CF antibody is detectable within the first week, while NT antibody is not found until the second or third week (Drobyshevskaya, 1954a) Neutralizing antibody endures at significant or high levels for at least 5 years (Buescher et al, 1958) if not for life CF antibody usually reaches a maximum by the third week and declines after 2 months to reach insignificant levels by 5 months (Southam, 1956). In some individuals, however, CF antibody may persist at relatively low titer for at least 5 years (Buescher et al, 1958) HI antibody reaches a maximum by 2 weeks, drops sharply after 5 or 6 months but is still detectable for several years (Southam, 1956).

Transplacental and transovarial transfer of maternal antibody has been demonstrated in mammals and birds In man, such passively acquired antibody disappears by the end of the sixth month(Hale and Lee, 1954) The effect of such antibody in nature is shown by the immunity of newborn horses in epizootics and in the prevention of the viremia in nestling birds, which is a potential source of vector infection

cortical gray matter, basal nuclei, pons and medulla Microscopically are seen perivascular cuffing and meningeal infiltration, chiefly with lymphocytes and some polymorphonuclear leukocytes Neuronal degeneration and necrosis with associated neuronophagia are noted, especially in the substantia nigra, red nuclei, basal ganglia, cerebral cortex, cerebellar cortex and horns of the spinal cord, along with diffuse or focal infiltration of various parts of brain and cord with mononuclear and polymorphonuclear cells The most striking pathologic change is the destruction of the Purkinje cells in the cerebellum, a lesion also observed in the experimental disease and in Russian tick-borne encephalitis In addition, there are patches of encephalomalacia, acellular plaques of spongy appearance in which medullary fibers, dendrites and axons are destroyed, and focal microglial proliferation In chronic cases, focal and diffuse deposition of calcium salts leading to a foreign body response may occur (Zimmerman, 1946) The topography of the lesions in all regions of the cortical gray matter and in the molecular and Purkinje cell layers of the cerebellum is different from that observed in poliomyelitis (Haymaker and Sabin, 1947) More detailed descriptions are given by Zimmerman (1946), Wolf (1950), Tigertt and Hammon (1950) and Lincoln and Sivertson (1952)

St. Louis virus Peripheral inoculation produces an inapparent, immunizing infection

Hamsters develop a fatal infection after intracerebral inoculation but usually show only viremia when infected by extraneural routes. Guinea pigs and rabbits exhibit a silent infection after inoculation by any route, according to recent experience, although earlier results of Japanese investigators indicated that rabbits succumbed to intracerebral inoculation Peripheral inoculation of monkeys, hamsters, guinea pigs and rabbits is a useful procedure for the production of immune serum

A wide variety of domestic animals, domestic fowl and wild birds develop inapparent infections frequently associated with significant viremia This is of epidemiologic significance as providing potential sources of virus for vector infection Horses infected in nature may develop encephalitis, and epizootics among them occur, although the majority have inapparent infections Sows, when experimentally infected early in pregnancy, exhibit a viremia and may produce stillborn or abnormal young, although the dams remain well (Shimizu et al, 1954) In Japan, a high incidence of stillbirths in swine has been associated with outbreaks of Japanese B encephalitis in human beings and horses, and

EXPERIMENTAL INFECTION, HOST RANGE

Japanese B closely resembles the St Louis virus in its effect upon the albino Swiss mouse The intracerebral is the route of choice for inoculation of mice of any age, and mice succumb to the disease when inoculated with dilutions of mouse-adapted virus up to 10^{-8} or occasionally higher Suckling mice are more susceptible to infection by extraneural routes than are older mice, which forms the basis for a highly sensitive type of neutralization test (see above, St. Louis virus) The disease picture in mice is one of a rapidly developing, lethal encephalomyelitis with paralyses, tremors and convulsions beginning in 3 to 8 days after inoculation

Rhesus and cynomolgus monkeys can develop a fatal encephalitis following intracerebral inoculation. The virus can be propagated indefinitely by monkey-to-monkey passage, in which respect this agent differs from

mental infection, a viremia of 2 to 5 days' duration consistently follows the infection of a variety of recently hatched wild and domestic birds. The infection is otherwise silent (Hammon et al, 1951b, Buescher, 1956) At least 2 species of bats, following subcutaneous inoculation, show a nonlethal infection characterized in some instances by very prolonged viremia (Corristan et al, 1956).

Various investigators, including Taniguchi et al., 1936, and Warren and Hough, and Koprowski and Cox, both 1946, showed that the virus can be cultivated in and is pathogenic for embryonated hens' eggs. Smith and Herring (1956) reported that the yolk-sac route of inoculation of 10-day eggs is a more rapid and sensitive method of titration than is the usual procedure of intracerebral inoculation in mice, and that it offers approxi-

shown by serum surveys in Korea and Okinawa (Deuel et al, 1950, Tigertt and Hammon, 1950) and in Malaya and Borneo (Pond et al., 1954, Hale et al, 1956, Federation of Malaya, 1957). Significant or high rates of immunity have also been found in various other parts of continental far-east Asia and on the Pacific islands within the broad endemic band described earlier The recognition of the probable presence of the virus in southern India by antibody survey (Smithburn et al, 1954a) has been confirmed by the diagnosis of a small outbreak of encephalitis in Madras State (Work and Shah, 1956) and the isolation of the virus from mosquitoes in the same area (Work, personal communication)

The occurrence of the disease is confined to the warmer months in temperate regions, and in certain of these areas severe epidemics recur at irregular intervals In warmer climates, cases may occur sporadically and unrelated to season The recent outbreak in India appears to have followed a period of unusually heavy rainfall, resulting in conditions especially favorable for mosquito breeding (Work and Shah 1956)

In some of the Japanese epidemics, a wide age distribution of cases has been seen with more than half of the patients over 50 years of age In other epidemics in Japan, and in Okinawa and Korea, the majority of cases occurred in children (Tigertt and Hamman, 1950, Hullinghorst et al, 1951) Only children were found to have the clinical disease in India (Work and Shah, 1956), and sporadic cases in other areas have been either in native children or in individuals recently entering the endemic region The obvious explanation of these findings lies in the high rates of immunity disclosed by antibody surveys in endemic zones so that only children, or adults recently entering the areas, comprise the population at significant risk There appears to be no relationship between sex and the case distribution The mortality rate is impossible to assess due to the number of inapparent or mild infections which escape diagnosis The case-fatality rate has been reported to be as high as 80 per cent in older age groups, and even in recent outbreaks mainly involving younger patients, the rate has been 35 to 44 per cent (Tigertt and Hammon, 1950, Hullinghorst et al, 1951) Tigertt and Hammon (1950) estimate 28 per cent as the case-fatality rate in United States armed forces personnel in Okinawa, 1945-1949, while in a larger outbreak involving American troops in Korea in 1950, a fatal outcome occurred in 10 per cent of the diagnosed cases (Dickerson et al, 1952) Age and the quality of nursing care are believed to be significant factors in influencing the outcome.

The close association of the epidemic disease with the seasonal incidence of culicine mosquitoes suggested to Japanese epidemiologists in the early 1930's that the infection was mosquito-borne, and in subsequent years, Mitamura and his associates recovered the virus from several *culicine* species, including *Culex tritaeniorhynchus;* and Japanese, Russian and American workers reported the experimental infection of many species of mosquitoes in several genera (reviewed by Hammon, Rees et al, 1949, and Day and Bennetts, 1954) Hammon, Rees et al (1949) confirmed earlier Japanese findings of the experimental transmission of the virus by *C tritaeniorhynchus* and *C pipiens* and reported additional isolations of the virus from naturally infected *C tritaeniorhynchus* (Hammon, Tigertt et al, 1949) Since that time, extensive studies by the scientific staff of the 406 Medical General Laboratory, maintained by the United States armed forces in Tokyo, have indicated that *C tritaeniorhynchus* is probably the sole vector of the human disease in the Tokyo area and perhaps in all Japan as well (Buescher, 1956) Investigation of the Malaysian form of *C tritaeniorhynchus* has shown it capable of experimental transmission of the virus (Hale et al., 1957), but of 10 recent isolations of virus from mosquitoes by the U S Army Medical Research Unit in Malaya only 3 were from this mosquito, while 7 were from *C gelidus* (Federation of Malaya, 1957) The mosquito species found naturally infected in the area of the recent outbreak in India was *C vishnui* (Work, personal communication) It seems probable that the chief vector, or vectors, vary in different areas, and such variations may be of major importance in understanding the different epidemiologic pictures The demonstration by Reeves and Hammon (1946) that the virus can be experi-

Diagnosis

A specific diagnosis can be made only by virus isolation or serologic tests, since the clinical picture, although suggestive in an epidemic, shares many features in common with other febrile diseases and infections of the CNS Virus isolation is of value for human diagnosis only in persons dying early in the disease It is frequently possible to isolate and characterize the virus from CNS tissue in the same manner as for St Louis virus Although Japanese and Soviet investigators have reported virus isolations from the blood of patients, this appears to be a most uncommon finding.

Diagnosis more commonly rests on the demonstration of a rise in specific antibodies as for St Louis virus infection In most of the endemic areas Japanese B is the only Group B virus now known to cause encephalitis in man. However, there is some overlap in the distribution of Japanese B and Russian tick-borne encephalitis in eastern Siberia, and the question of the possible occurrence of both Japanese B and Murray Valley viruses in India has not yet been resolved. Therefore, the problem of the diagnosis of infections with obvious CNS manifestations is, in most areas, somewhat analogous to that of St Louis virus in North America However, outbreaks of dengue have been recognized to occur in many of the same areas as do infections with Japanese B virus, including Japan and Malaya. The possible complicating effect of the co-existence of two related viruses on serologic diagnosis must be kept in mind (see above) In an outbreak of dengue in Malaya, Smith (1957) found that the serologic response as measured by both the CF and HI tests was similar with dengue and Japanese B antigens and considered the NT test the only reliable serologic procedure On the other hand, studies of confirmed cases of West Nile fever in Israel by Goldblum et al. (1957) showed almost equally high titer NT antibodies for West Nile and Japanese B viruses, although there is no reason to believe that the latter infection occurs in that area These investigators found the CF test to be much more specific than the NT test. In an area in India from which both West Nile and Japanese B viruses have been isolated, the CF test proved to be sufficiently reliable to establish the diagnosis of a small outbreak of Japanese B encephalitis (Work and Shah, 1956). In Japan, Korea and Okinawa, the CF test has been found more satisfactory than the NT for the diagnosis of clinical infections Not only is the CF the more practical test, but the slower rise in CF antibody increases the probability that the initial specimen will be negative or show a significantly lower titer than subsequent ones. In some cases, several weeks may be required for the development of CF antibody, and occasionally it may fail to develop at all (Sabin, 1947; Dickerson et al, 1952, Southam, 1956a) Southam (1956a) states that the HI test is uniquely valuable in Japan, since it is diagnostically positive at an earlier time and is as simple as and more reliable than the CF test. Experience with the HI test is limited outside of Japan, but it tends, in general, to be the least specific of the 3 procedures for Group B infections. Therefore, it would appear essential to employ more than one type of test and several related viruses or antigens in establishing a diagnosis whenever past or present infection with a related virus is a reasonable possibility. This is particularly true for the diagnosis of mild infections or for serum survey for the incidence of past infections As discussed earlier and in Chapter 12, the serologic response is extremely complex when an infection is superimposed on past experience with a related virus; a specific diagnosis may then be impossible

Treatment

No specific treatment is available Comprehensive supportive and nursing care are extremely important for all seriously ill patients, and fairly prolonged hospitalization may be necessary during the slow convalescence.

Epidemiology

As is true with St. Louis virus, Japanese B virus produces a high incidence of inapparent infections in man. This has been demonstrated in surveys in Japan by Bawell et al (1950) and by Southam (1956b) From studies on Japanese children, the latter investigator estimates that about 10 per cent become infected annually and that 500 to 1,000 inapparent infections develop for each case of clinically apparent disease Similar high inapparent-infection rates have been

shown by serum surveys in Korea and Okinawa (Deuel et al, 1950, Tigertt and Hammon, 1950) and in Malaya and Borneo (Pond et al., 1954; Hale et al, 1956; Federation of Malaya, 1957). Significant or high rates of immunity have also been found in various other parts of continental far-east Asia and on the Pacific islands within the broad endemic band described earlier The recognition of the probable presence of the virus in southern India by antibody survey (Smithburn et al, 1954a) has been confirmed by the diagnosis of a small outbreak of encephalitis in Madras State (Work and Shah, 1956) and the isolation of the virus from mosquitoes in the same area (Work, personal communication)

The occurrence of the disease is confined to the warmer months in temperate regions, and in certain of these areas severe epidemics recur at irregular intervals In warmer climates, cases may occur sporadically and unrelated to season. The recent outbreak in India appears to have followed a period of unusually heavy rainfall, resulting in conditions especially favorable for mosquito breeding (Work and Shah, 1956)

In some of the Japanese epidemics, a wide age distribution of cases has been seen with more than half of the patients over 50 years of age In other epidemics in Japan, and in Okinawa and Korea, the majority of cases occurred in children (Tigertt and Hamman, 1950, Hullinghorst et al, 1951) Only children were found to have the clinical disease in India (Work and Shah, 1956), and sporadic cases in other areas have been either in native children or in individuals recently entering the endemic region The obvious explanation of these findings lies in the high rates of immunity disclosed by antibody surveys in endemic zones so that only children, or adults recently entering the areas, comprise the population at significant risk There appears to be no relationship between sex and the case distribution The mortality rate is impossible to assess due to the number of inapparent or mild infections which escape diagnosis The case-fatality rate has been reported to be as high as 80 per cent in older age groups, and even in recent outbreaks mainly involving younger patients, the rate has been 35 to 44 per cent (Tigertt and Hammon, 1950; Hullinghorst et al, 1951). Tigertt and Hammon (1950) estimate 28 per cent as the case-fatality rate in United States armed forces personnel in Okinawa, 1945-1949, while in a larger outbreak involving American troops in Korea in 1950, a fatal outcome occurred in 10 per cent of the diagnosed cases (Dickerson et al, 1952) Age and the quality of nursing care are believed to be significant factors in influencing the outcome.

The close association of the epidemic disease with the seasonal incidence of culicine mosquitoes suggested to Japanese epidemiologists in the early 1930's that the infection was mosquito-borne, and in subsequent years, Mitamura and his associates recovered the virus from several *culicine* species, including *Culex tritaeniorhynchus*, and Japanese, Russian and American workers reported the experimental infection of many species of mosquitoes in several genera (reviewed by Hammon, Rees et al, 1949, and Day and Bennetts, 1954) Hammon, Rees et al (1949) confirmed earlier Japanese findings of the experimental transmission of the virus by *C. tritaeniorhynchus* and *C pipiens* and reported additional isolations of the virus from naturally infected *C tritaeniorhynchus* (Hammon, Tigertt et al, 1949) Since that time, extensive studies by the scientific staff of the 406 Medical General Laboratory, maintained by the United States armed forces in Tokyo, have indicated that *C tritaeniorhynchus* is probably the sole vector of the human disease in the Tokyo area and perhaps in all Japan as well (Buescher, 1956) Investigation of the Malaysian form of *C tritaeniorhynchus* has shown it capable of experimental transmission of the virus (Hale et al, 1957), but of 10 recent isolations of virus from mosquitoes by the U S Army Medical Research Unit in Malaya only 3 were from this mosquito, while 7 were from *C gelidus* (Federation of Malaya, 1957) The mosquito species found naturally infected in the area of the recent outbreak in India was *C vishnui* (Work, personal communication) It seems probable that the chief vector, or vectors, vary in different areas, and such variations may be of major importance in understanding the different epidemiologic pictures The demonstration by Reeves and Hammon (1946) that the virus can be experi-

mentally transmitted by 7 species, representing 3 genera, of mosquitoes indigenous to North America indicates the theoretical possibility that the virus could be disseminated in the Western Hemisphere. As to the possible role of mites as vectors, Reeves et al. (1955) failed to obtain experimental evidence for the potential importance of the chicken mite, and they quote the unpublished studies of Hammon and Tigertt in 1953 in endemic areas of Japan in which no virus was isolated from many thousands of mites collected in wild birds' nests

The reservoirs of the virus remain unknown, although the observation of Hurlbut (1950) that experimentally infected mosquitoes can transmit the virus after hibernation at low temperatures for at least 82 days suggests one possible mechanism for survival of the virus during the winter in temperate zone environments. A number of surveys in various endemic areas have shown a high incidence of antibody in the blood of such domestic animals as horses, pigs, cattle, goats, sheep and dogs (Bawell et al, 1950, Tigertt and Hammon, 1950, Hullinghorst et al, 1951, Pond et al, 1954, Drobyshevskaya and Sokolov, 1954) Drobyshevskaya (1954b) reported the isolation of Japanese B virus from the blood of 3 of 280 human beings and 2 of 83 horses in an endemic area during the epidemic season, while a somewhat larger series in the pre-epidemic period was entirely negative. It is of interest that the human donors were and remained well. Despite these observations, it is unlikely that man and domestic animals play an important role in virus dissemination because the high immunity rates and relatively slow population turnovers result in the presence of relatively few individuals capable of developing viremia for vector infection

The probable important epidemiologic role of nestling wild birds, especially of the heron family, in the rapid seeding of the vector population in the Tokyo area of Japan has been well demonstrated (Buescher, 1956). The studies showed a relationship between the instance of viremia in heron nestlings, the frequency of mosquito infection and the occurrence of encephalitis in human beings and animals Serum surveys have shown a high or significant incidence of antibody in the blood of a variety of species of wild birds (Hammon et al, 1951b; Buescher, 1956; Smorodintsev et al., 1954b). Since the wild-bird population turnover is rapid, there is available annually a large number of new susceptible nestlings, and these birds consistently develop a viremia of several days' duration following infection. The wild bird appears to be of importance as a disseminator of both St. Louis and Japanese B viruses, and this also appears to be true of the Murray Valley virus Of probable significance is the fact that quite unlike the situation with both St. Louis and Murray Valley viruses, the domestic chicken appears to escape infection with Japanese B virus completely, although it is readily infected experimentally.

One peculiar epidemiologic observation is that extensive dissemination of the virus can occur among domestic animals in endemic regions of Japan in the absence of human epidemics and, conversely, epidemics have occurred without associated epizootics (Sabin et al, 1947, Burns et al., 1949, Buescher, 1956) This suggests the presence of at least two different epidemiologic cycles which can operate quite independently.

CONTROL

The main attempts to control the disease have been by means of formalin-inactivated vaccines Vaccination has been practiced by the Russians since 1941, using a mouse-brain preparation In the United States, a formalinized mouse-brain vaccine was developed by Sabin et al, 1943, and Warren and Hough, and Koprowski and Cox, both 1946, reported on the preparation of an inactivated vaccine from infected chick embryos Smadel et al (1947) described the chick embryo vaccine subsequently used in the Far East Both types of vaccine were used extensively from 1945 to 1951 for immunization of U S armed forces personnel and for field trials involving many thousands of Japanese school children The results of the field trials are reviewed briefly in a recent article by Tigertt and Berge (1957) in which references are given to more detailed reports on evaluation of the vaccine. The study was handicapped because no large outbreaks of the disease occurred during the period of investigation, but the final cautious estimate was that the results indicated some degree of protection This was

based both on serologic studies and on a lower incidence of the disease in the vaccinated as compared with the control series for the entire study period Unmodified cases did occur among vaccinated children Evaluation of the results of vaccination of U S personnel was difficult to assess, but the effectiveness of the vaccines was considered sufficiently dubious that routine vaccination was discontinued in 1951. So far, efforts directed toward the development of a more potent and stable vaccine have met with no success (Pond and Smadel, 1954)

Vector control offers a logical approach when it is feasible Much more needs to be learned of the epidemiology of the disease in each endemic area before practical programs of control can be achieved

MURRAY VALLEY ENCEPHALITIS

(SYNONYM. Australian X Disease)

INTRODUCTION

Australian investigators appear to agree generally that Murray Valley encephalitis and Australian X disease are one and the same, and they will be so considered here. Although the opinion has been expressed that Murray Valley virus could be a variant strain of Japanese B, sufficient evidence is available to justify its designation as a distinct entity within the subgroup described earlier in the chapter, even though a close immunologic relationship exists between the Murray Valley and Japanese B viruses

HISTORY

During the summer of 1917-1918 an epidemic of acute encephalitis broke out in Australia, involving 134 persons of whom half were less than 5 years of age, 70 per cent succumbed to the disease, Cleland and Campbell, 1917 The disease reappeared in 1922, 1925 and 1926 in milder form but not again until 1951 A virus was isolated from the brains of 3 patients by Cleland and Campbell, 1917, 1919 but was lost before a comparative study of its properties could be made These early outbreaks were designated Australian X disease

In 1951 an epidemic of encephalitis again occurred in eastern Australia in the valleys of the Murray and the Darling Rivers in Victoria and New South Wales There were 40 recognized severe cases of which more than half were children, and there were 17 deaths Later studies showed a high rate of mild or inapparent infection. The disease was named Murray Valley encephalitis, and the virus was isolated from the brains of several fatal cases by French (1952) and by Miles et al (1951). The evidence for considering Australian X disease and Murray Valley encephalitis to be identical is discussed by Burnet (1952), and the serologic studies of McLean and Stevenson (1954) lend support to the concept There have been no reported epidemics since 1951

CLINICAL AND PATHOLOGIC PICTURES

Clinically and pathologically, the disease closely resembles that following Japanese B virus infection (Robertson and McLorinan, 1952, Robertson, 1952) Cases vary from a mild illness to severe and fatal encephalitis The disease tends to be more severe in the very young The onset is typically abrupt, with malaise, headache, fever and irritability Lethargy, drowsiness and gastro-intestinal manifestations occur early, as do convulsions in young children In severe cases cerebration and consciousness become progressively impaired, this occurs rapidly in children but more gradually in adults Cervical rigidity is a constant finding Improvement may occur at any stage and lead to rapid and complete recovery if it occurs early, but frequently the disease is progressive Tremors, involuntary movements, pareses, paralyses and respiratory arrhythmia are features of the severe illness The most common residua are impairment of cerebral function, paralyses and personality changes In fatal cases death may occur early or after prolonged illness The cerebrospinal fluid shows a moderate pleocytosis ranging from 20 to 750 cells, averaging around 100 Protein may be slightly elevated

The primary pathologic change is neuronal damage with secondary degeneration of nerve fibers Neurons throughout the entire CNS are involved, destruction of Purkinje cells being especially striking The spinal cord changes closely resemble those of poliomyelitis (Garven and Margolis 1952). The proliferative and infiltrative response resembles that of other arbor virus encephalitides. The

lesions are both diffuse and localized. In chronic stages of the disease areas of total necrosis are seen, and deposition of calcium salts may be found

Experimental Infection; Host Range, Etiology, Diagnosis

Two out of 3 of the initial Murray Valley virus isolations by French (1952) were successful only by chorio-allantoic membrane inoculation of chick embryos, and the presence of virus was recognized only by the occurrence of a few pocks on the membrane. The third isolation was successful, both in chick embryos and by intracerebral inoculation of mice. French suggests that the demonstration of pocks on the chorio-allantoic membrane is the most sensitive indicator of the presence of the virus and can yield positive results when virus cannot be demonstrated by other technics

The virus is highly pathogenic for chick embryos inoculated by the amniotic, the allantoic and the yolk-sac routes, and death occurs in 3 days with characteristic pathologic changes and the occurrence of virus in various tissues and fluids It is also highly pathogenic for adult and suckling mice by the intracerebral route and for suckling mice by extraneural routes The picture in mice is characterized by convulsions, in-co-ordination, tremor and paralysis of the hind limbs. The titer of virus in the brain is high, and it is readily transmitted serially (French, 1952).

The rhesus monkey develops encephalitis and succumbs after intracerebral inoculation but shows no reaction following subcutaneous inoculation. Rabbits and guinea pigs show essentially silent, immunizing infections, except for a febrile response in the latter, after inoculation by any route (French, 1952, Miles, 1952) The virus readily produces a fatal infection in hamsters on extraneural as well as intracerebral inoculation, in which respect it resembles West Nile virus and differs from Japanese B and St. Louis viruses (Hammon and Sather, 1956) Various domestic animals, fowl and wild birds are susceptible to infections with the virus and may succumb following intracerebral inoculation. Most frequently, the response to peripheral inoculation consists of the development of viremia and subsequently of antibodies (French, 1952; Miles, 1952). The young chick is particularly susceptible to infection and regularly develops a viremia following peripheral inoculation; the infection is otherwise silent (McLean, 1953a). It provides a useful tool for entomologic studies and is believed to be of epidemiologic importance as a source for vector infection.

The immunologic basis for placing the virus in Group B is discussed in Chapter 12; the other members of the subgroup closely related to Murray Valley virus are indicated above. Australian investigators recognized a close relationship between Murray Valley and Japanese B viruses but considered them to be distinct The detailed studies of Pond and his associates (1955) confirm the lack of identity between the two and provide evidence that the virus endemic in southeast Asia is Japanese B and not Murray Valley. The virus is 20 to 50 mμ in diameter by gradocol membrane filtration (Miles, 1952) The conditions for preservation of the virus are the same as those described for St. Louis and Japanese B viruses MacDonald (1952) described a hemagglutinin in saline extracts of infected suckling mouse brain which was demonstrable with erythrocytes of the pigeon or the day-old chick. McLean (1956) prepared the hemagglutinin by acetone-ether extraction of suckling mouse brain according to the procedure of Casals and Brown (1954) The infective and hemagglutinating properties can be partially purified by protamine sulfate treatment as described for St Louis and Japanese B viruses

Neutralizing (NT), complement-fixing (CF) and hemagglutination-inhibiting (HI) antibodies develop after infection, although the HI test has not yet been applied to the study of natural infections As is true with other members of the group, the CF antibody is less enduring than the NT and has been used as an indicator of recent infection (Anderson et al, 1952, Miles, 1955; Miles and Dane, 1956)

Specific diagnosis rests upon virus isolation from CNS tissue or upon demonstration of the development of homologous antibodies in association with the disease. The principles are the same as those outlined for St Louis and Japanese B infections Since extensive epidemics of dengue have occurred in the same

general areas as do Murray Valley infections, the problem of serologic diagnosis resembles that of Japanese B (see above) The group relationships make the interpretation of serum surveys for past infection especially difficult, for example, Miles and Dane (1956) recognize the possibility that their surveys in the Northern Territory of Australia may have been complicated by the presence of dengue infection but give reasons for believing that this was not the case

Treatment; Epidemiology, Control

There is no specific treatment.

Murray Valley virus has the arbor virus characteristic of producing a high incidence of inapparent infections in man and infects a high proportion of horses without producing evidence of disease (Anderson et al, 1952; Miles and Howes, 1953). It is estimated that inapparent infections in man are 500 to 1,000 times more common than clinically demonstrable cases (Anderson et al, 1952, Burnet, 1952) This estimate is identical with that given by Southam for Japanese B virus infections in Japan (see above) Although all ages may be attacked, the clinical disease is seen in children with particular frequency A fatal outcome is obviously uncommon in relation to total infection rates, but the diagnosed case fatality rate is high

Outbreaks of the disease have occurred in the Murray-Darling basin in Victoria and New South Wales, but on the basis of serologic surveys, the infection is believed to be widely distributed throughout eastern Australia and endemic in the Northern Territory and Queensland (Burnet, 1952, Miles and Howes, 1953) Studies in both 1952 and 1954 revealed that 80 to 90 per cent of the aborigines in certain areas in the Northern Territory have antibody to the virus, and it is suggested that this virus may be the cause of some of the sporadic cases of severe encephalitis seen there (Miles and Dane, 1956) Earlier serologic studies suggested the presence of the virus in New Guinea, and recently it was isolated from the brain of a fatal case of encephalitis (French et al, 1957) Due to group relationships, it is still not clear whether or not Murray Valley virus infections have occurred in India (Smithburn et al, 1954a) The studies of Pond et al (1955) indicate that the neutralization of Murray Valley virus by human sera from Malaya and Borneo can be attributed to previous infection with Japanese B virus

The virus has not been isolated from naturally infected mosquitoes, but attempts have not yet been made during the peak of an epidemic Experimental infection of and transmission by various mosquito species is discussed by McLean (1953b; 1957), who also presents evidence for the belief that *Culex annulirostris* is the principal vector.

The following concept of the epidemiology of the disease is based on discussions by Anderson (1953), Anderson and Eagle (1953), Miles and Howes (1953), and Miles and Dane (1956) The infection is probably endemic in the Northern Territory, Queensland and perhaps northern New South Wales where the virus is believed to be maintained throughout the year by a wild bird-mosquito cycle When meteorologic conditions are especially favorable, the infection may break out of the endemic areas and be brought into the southeast by a chain of migratory bird-mosquito-bird cycles Once introduced into the southern epidemic region, the domestic fowl probably plays an important role in human disease as a source of vector infection

A striking correlation has been observed between the years of excessive rainfall in the Northern Territory and Queensland and the subsequent appearance of epidemics in the south It is suggested that such meteorologic data should give warning of the imminence of future outbreaks (Miles and Howes, 1953) Control measures might then be instituted, although the lack of a vaccine and inadequate knowledge of the chief vectors make practical control problematical

WEST NILE FEVER

Antibody surveys indicate that West Nile virus infection may be widespread in Africa, including East, West and Central Africa and the plateau region of South Africa It is a highly endemic infection in Egypt and has been discovered to be the cause of recurrent epidemics of a denguelike disease in Israel It occurs in India, as has been demonstrated both by antibody surveys and virus isolation

The virus was first isolated from the blood of a native of Uganda who was suffering from

a mild febrile illness, Smithburn et al, 1940 Later, it was isolated from the blood of 3 Egyptian children by Melnick et al (1951) Subsequently, isolations were made by Taylor et al (1956) from human blood, mosquitoes and birds in Egypt. Bernkopf et al. (1953) first diagnosed the epidemic disease in Israel by virus isolation from a patient.

Clinical Picture

The following description is drawn from reports of recent epidemics in Israel by Bernkopf et al (1953), Goldblum et al. (1954) and Marburg et al (1956) Mild, atypical and abortive cases are known to occur The clinically recognizable infection is a self-limited, nonfatal disease which closely resembles dengue fever The incubation period is 3 to 6 days. The onset is always sudden, and the characteristic findings are fever, severe headache, rash and generalized lymphadenopathy The rash is pinkish, discrete and maculopapular, occurring mainly on the trunk and not followed by desquamation Other common manifestations are malaise, generalized myalgias, ocular pain, gastro-intestinal disturbances, flushed face, injected conjunctivae and reddening and soreness of the throat In some cases, a biphasic temperature curve is seen with a recurrence of symptoms in milder form in association with the secondary temperature rise The blood shows a leukopenia with a relative lymphocytosis and shift to the left In a very small percentage of cases, slight transitory meningeal involvement occurs, and in such cases the cerebrospinal fluid shows a pleocytosis and increase in protein However, West Nile virus is an uncommon cause of aseptic meningitis in Israel The acute phase lasts, as a rule, for 3 to 5 days, with extremes of 1 to 12 days There have been no fatalities and no sequelae Recovery is more rapid in children than in adults, who may show persistent weakness and fatigue for one to several weeks

Southam and Moore (1954a) reported on the use of recently isolated strains of West Nile virus for therapeutic trials in patients with advanced malignant neoplasia Nine of 78 patients had definite or suggestive evidence of diffuse encephalitis attributable to the virus infection. These observations coupled with the occasional occurrence of meningeal involvement in the course of natural infections indicate that the virus is potentially capable of infecting the human CNS

Experimental Infection; Host Range

West Nile virus affects common laboratory animals in a manner similar to the related viruses described above. The albino Swiss mouse is highly susceptible to intracerebral inoculation, and lethal encephalitis ensues after 3 to 8 days The titer of virus in the brain is of the order of 10^{-8}, and the virus is readily maintained by serial passage Suckling mice are much more susceptible to peripheral inoculation than are adults The virus causes encephalitis and death in rhesus monkeys on intracerebral inoculation but only produces fever and immunity following intravenous administration It immunizes but is not pathogenic for rabbits and guinea pigs Hamsters are susceptible to both intracerebral and peripheral inoculation, in which respect the virus resembles Murray Valley and differs from St. Louis and Japanese B viruses (Hammon and Sather, 1956) Various domestic animals experience inapparent immunizing infections with low levels of viremia in some instances (Taylor et al., 1956).

The domestic chicken and pigeon and various wild birds can be infected by peripheral routes and develop viremia of varying degree (Work et al, 1955; Taylor et al, 1956) The infection may or may not be fatal The susceptibility of the chicken is related to age, young chicks readily acquire the infection and circulate the virus in fairly high titer In young chicks of at least one strain, successful infection by any route has led invariably to a fatal outcome (Whitman, personal communication) Older chickens become partially or completely refractory to infection West Nile resembles the related viruses in the importance of avian species in the epidemiology of the infections it induces.

Watson, 1943, Taylor (1952), and Fendrich et al (1957), described cultivation of the virus in chick embryos. Death of infected embryos occurs with such regularity that the virus can be titrated in eggs as well as in mice Taylor found the yolk-sac route of inoculation to be simple and satisfactory, but Fendrich et al considered the intravenous the route of choice. Bernkopf et al. (1953) observed

pocks on the membrane following chorio-allantoic membrane inoculation but did not find this a satisfactory method either for initial virus detection or virus titration

The virus adversely affects or is oncolytic for a variety of tumors, both of man and lower animals, grown in experimental animals (Sharpless et al, 1950, Koprowski and Norton, 1950, Toolan and Moore, 1952; Koprowski, 1956, and Moore, 1957) When administered to human beings with advanced malignant neoplasia, the virus was never curative but produced, in some cases, a transitory inhibitory effect on tumor growth (Southam and Moore, 1952).

The virus can be grown in Maitland type of tissue culture, Lennette and Koprowski, 1946. It is regularly cytopathogenic for HeLa cells, chick embryo fibroblasts and monkey kidney epithelial cells in tissue culture (Scherer and Syverton, 1954, Bhatt and Work, 1957) and grows, with variable cytopathic effects, in a variety of other cell lines (Moore, 1957).

Etiology and Diagnosis

The basis for the classification of the virus in Group B has been discussed in Chapter 12 and in this chapter. The diameter of the virus is 20 to 30 mμ, as determined by gradocol membrane filtration (Smithburn and Bugher, 1953) It has the same properties as do St Louis and Japanese B viruses, and the same conditions apply to its preservation (see above). A hemagglutinin in saline extracts of infected mouse brain was first reported by Sabin, 1951, and subsequently in acetone-ether extracted suckling mouse brain by Casals and Brown (1954) The hemagglutinin also has the same properties as do those of related viruses Neither infective nor hemagglutinating activities are precipitated by protamine sulfate (Warren et al, 1949, Clarke, unpublished results)

Neutralizing (NT), complement-fixing (CF) and hemagglutination-inhibiting (HI) antibodies develop following infection Goldblum et al (1957) in a study of over 300 patients in Israel found that CF antibody was first demonstrable in the second week, reached a maximum at 2 to 3 weeks and began to decline after 7 months to reach very low levels at 2½ years They report that NT antibody was detectable in only half the cases in 2 to 3 weeks, although it was present in high titer in all at 2 to 3 months and persisted at a high level for at least 2½ years These investigators observed serious loss in both CF and NT antibodies on storage of specimens in a commercial deep freeze In a study of induced infections in man, Southam and Moore (1954b) observed no marked differences in the rate of development of CF, NT and HI antibodies, which were all usually detectable 3 to 4 weeks after infection They considered all 3 technics to be equally satisfactory

Accurate diagnosis rests on virus isolation or the demonstration of a rise in specific antibody in association with the infection The clinical features of the disease do not sharply delineate it from other entities, and the disease has been mistaken for dengue Unlike infections with members of the Group previously discussed, virus isolation is frequently a practical diagnostic procedure When repeated blood specimens were obtained during the early phase of the disease, as many as 38 per cent of cases have been so diagnosed, and 77 per cent when a specimen was secured on the first day (Goldblum et al, 1957) The technic for virus isolation and identification is similar to that for St Louis virus (see above) except that the specimen consists of blood serum rather than CNS tissue Virus has not been isolated from spinal fluid, throat swabs or stools following natural infection When virus isolation fails, diagnosis rests on the demonstration of a rise in specific antibodies as described for St Louis infection The problem is complicated by the occurrence of group and subgroup relationships, and the use of more than one type of test and several related viruses or antigens is indicated if past or present infection with a related virus is a reasonable possibility Goldblum et al (1957) found that confirmed cases of West Nile fever develop NT antibodies to approximately equal titer against West Nile and Japanese B viruses, and Taylor et al (1956) reported that similar sera from Egypt neutralized both Japanese B and Ntaya viruses Goldblum found the CF test much more reliable than the NT The HI test is even less specific than the NT, but when performed under controlled conditions with a variety of related antigens,

the homologous titer is found to be, in general, higher than the heterologous A tentative diagnosis can be made from the HI pattern of response, but confirmation is required by other procedures (Casals and Theiler, personal communication)

TREATMENT, EPIDEMIOLOGY, CONTROL

Treatment is entirely symptomatic.

Present knowledge of the epidemiology of infections with West Nile virus comes from two different sources Israel, where the disease is recurrently epidemic, and Egypt, where the infection is highly endemic and the disease goes unrecognized as a clinical entity In Israel, inapparent infection is unrelated to age as determined by serologic studies, and virus has been isolated from the blood of individuals who were at no time ill (Bernkopf et al, 1953; Goldblum et al., 1954; Goldblum et al, 1957)

In both Egypt and Israel, the infection is highly seasonal, and it is estimated that it is the cause of two thirds to three quarters of the "summer fevers" in Israel. There is evidence for the occurrence of occasional infection during the winter in the highly endemic areas of Egypt (Taylor et al, 1956, Goldblum et al, 1957). The virus has been isolated from man in Uganda, Egypt and Israel, and from mosquitoes and birds in Egypt A single isolation from *Culex molestus* mosquitoes is also recorded from Israel (Tahori et al, 1955). In India, its presence was first indicated by a significant incidence of NT antibody (Smithburn et al, 1954a), and later it was isolated from mosquitoes (Work, personal communication). In addition to the above localities, NT antibody has been reported to occur in the Sudan, Kenya, the Belgian Congo, Nigeria and the Union of South Africa (Smithburn and Jacobs, 1942, Smithburn, 1952; Dick, 1953, Kokernot et al, 1956)

The early acquisition of immunity in the endemic areas of Egypt causes West Nile fever to be a disease of early childhood there (Melnick et al, 1951, Taylor et al, 1956). In Israel, the case rate is highest in infants, but all ages are involved. There is no apparent influence of sex on the incidence of infection

Experimental transmission of the virus by mosquitoes was reported by Philip and Smadel, 1943, by Kitaoka, 1950, by Davies and Yoshpe-Purer, 1954, and by Hurlbut (1956) in the course of extensive investigations on West Nile infection in arthropods. Apart from these studies and the clinical and immunologic observations reported from Israel, most of the information regarding the epidemiology of the disease stems from the extensive studies in Egypt by Taylor et al (1956). Similar studies have not yet been reported from Israel, although there is some evidence that *Culex molestus* may be a vector there (Tahori et al., 1955). A concept of the ecology of the virus in Egypt was arrived at by virus isolations from man, birds and mosquitoes, by serologic studies in man, birds and other animals and by experimental infection of birds and other animals and of various arthropod species. The dominant cycle by which the virus is propagated is believed to be bird-mosquito-bird with *Culex univittatus* the principal vector. Some evidence was obtained that the virus may overwinter by means of a slow continuous cycle in which *Culex pipiens* is involved Human infection is widespread in those areas where mosquitoes prevail and occurs seasonally in relation to the presence of virus in mosquitoes Although viremia in man may be sufficient to infect mosquitoes, it seems unlikely, in view of the high immunity rate in the population, that a man-mosquito cycle is of importance. A wide range of other vertebrates is infected by the virus, but their infections are believed to be tangential or "dead-end."

Protection from, or control of, the vectors offers the only present approach to control of the disease

ILHEUS VIRUS INFECTION

Ilheus virus has been found in South and Central America and in Trinidad, B.W.I. It has been isolated from mosquitoes in Brazil, Honduras and Guatemala, and from both mosquitoes and man in Trinidad Serologic surveys indicate it to be a prevalent human infection in the Amazon valley in Brazil and in parts of Trinidad. This is not to imply that the virus does not occur elsewhere, but information is not available from other areas. It seems probable that the virus is limited to the Western Hemisphere.

Laemmert and Hughes (1947) first isolated the virus from forest mosquitoes in Brazil. Anderson et al. (1956) recovered the virus from forest mosquitoes in Trinidad, and further mosquito isolations have been reported from Honduras and Guatemala (de Rodaniche, 1956, de Rodaniche and Galindo, 1957) The virus has been recovered from human blood in Trinidad (Downs et al, 1956a, Anderson, Delpeche and Downs, personal communication).

Information on the clinical picture is meager. With regard to the two natural infections in Trinidad, one was in a patient bled on the second day of illness who subsequently developed an encephalitic reaction and was very ill for 2 weeks The other was a completely asymptomatic infection in a mosquito collector who had been working in the forest Infection of patients with advanced malignant neoplasia was tried by Southam and Moore (1951) for possible therapeutic effect, using mouse-brain adapted virus Of 9 successful infections, 6 were asymptomatic, but in 3, mild encephalitis ensued On this basis, the virus can be considered to have the characteristics of its group in producing both inapparent and clinically demonstrable reactions in man

The virus has the same properties as do the other members of the group Its subgroup relationship is given earlier in this chapter Its diameter by filtration is 18 to 26 mμ (Smithburn and Bugher, 1953) The albino Swiss mouse is the laboratory animal of choice, and the effect of age on susceptibility is the same as for related viruses. Other common laboratory animals, in general, show no visible reaction to but are immunized by the virus The virus multiplies in but does not kill the chick embryo unless massive doses are given, and it multiplies well in Maitland-type tissue culture Marmosets, some marsupials, and rodents develop somewhat sustained viremia after infection, which is of possible significance in dissemination of the virus For more detailed accounts, the reader is referred to reports of Koprowski and Hughes (1946), de Rodaniche (1956) and Taylor (1952) The virus parasitizes and in some cases adversely affects certain animal tumors in vivo (Koprowski and Norton, 1950, Koprowski, 1956) It grows in a variety of cell lines in tissue culture with variable cytopathogenicity (Moore, 1957) A hemagglutinin was described in acetone-ether extracted suckling-mouse brain by Casals and Brown (1954) and is readily demonstrable in alkaline aqueous extracts of such tissue. The latter preparation is improved by treatment with protamine sulfate, which precipitates neither infective nor hemagglutinating activities (Clarke, unpublished results).

The principles for the diagnosis of recent or past infection with the virus are the same as for related viruses and are discussed in Chapter 12 and in this chapter All 3 types of antibody, NT, CF and HI, develop following infection.

Some of the virus isolations from mosquitoes have been from lots containing 2 or more genera However, 3 of the 9 isolations were from lots made up of mosquitoes of the *Psorophora* genus only, in one case, only *Psorophora ferox* and in another mainly this species Laemmert and Hughes (1947) demonstrated experimental transmission of the virus by *P ferox* and by two *Aëdes* species. The probable importance of *Psorophora* species, in particular *P ferox*, as vectors is suggested The recent isolation in Guatemala was from *Sabethes chloropterus*

On the basis of serologic surveys in Trinidad, human infection with the virus appears to be common in lowland forested areas (Downs et al, 1956b) In a similar survey in the Amazon valley of Brazil, a high incidence of human infection was also indicated (Causey and Theiler, 1958). In both surveys, a significantly higher rate was found for males than for females, which is attributed to the more intimate contact of the former with the forest

RUSSIAN TICK-BORNE COMPLEX

Introduction and History

The viruses making up the Russian tick-borne complex will be treated as different strains of one virus and considered together despite the diverse clinical pictures resulting from infection Such a treatment was suggested by Pond et al (1953) as a result of [illegible]

hoped to clarify what is, at present, a confusing and poorly understood subject. Ulti-

the homologous titer is found to be, in general, higher than the heterologous A tentative diagnosis can be made from the HI pattern of response, but confirmation is required by other procedures (Casals and Theiler, personal communication)

TREATMENT, EPIDEMIOLOGY, CONTROL

Treatment is entirely symptomatic

Present knowledge of the epidemiology of infections with West Nile virus comes from two different sources· Israel, where the disease is recurrently epidemic, and Egypt, where the infection is highly endemic and the disease goes unrecognized as a clinical entity In Israel, inapparent infection is unrelated to age as determined by serologic studies, and virus has been isolated from the blood of individuals who were at no time ill (Bernkopf et al, 1953, Goldblum et al, 1954, Goldblum et al, 1957).

In both Egypt and Israel, the infection is highly seasonal, and it is estimated that it is the cause of two thirds to three quarters of the "summer fevers" in Israel There is evidence for the occurrence of occasional infection during the winter in the highly endemic areas of Egypt (Taylor et al, 1956, Goldblum et al, 1957) The virus has been isolated from man in Uganda, Egypt and Israel, and from mosquitoes and birds in Egypt. A single isolation from *Culex molestus* mosquitoes is also recorded from Israel (Tahori et al, 1955) In India, its presence was first indicated by a significant incidence of NT antibody (Smithburn et al, 1954a), and later it was isolated from mosquitoes (Work, personal communication) In addition to the above localities, NT antibody has been reported to occur in the Sudan, Kenya, the Belgian Congo, Nigeria and the Union of South Africa (Smithburn and Jacobs, 1942; Smithburn, 1952, Dick, 1953, Kokernot et al, 1956).

The early acquisition of immunity in the endemic areas of Egypt causes West Nile fever to be a disease of early childhood there (Melnick et al, 1951, Taylor et al., 1956). In Israel, the case rate is highest in infants, but all ages are involved There is no apparent influence of sex on the incidence of infection

Experimental transmission of the virus by mosquitoes was reported by Philip and Smadel, 1943, by Kitaoka, 1950, by Davies and Yoshpe-Purer, 1954, and by Hurlbut (1956) in the course of extensive investigations on West Nile infection in arthropods Apart from these studies and the clinical and immunologic observations reported from Israel, most of the information regarding the epidemiology of the disease stems from the extensive studies in Egypt by Taylor et al (1956) Similar studies have not yet been reported from Israel, although there is some evidence that *Culex molestus* may be a vector there (Tahori et al., 1955). A concept of the ecology of the virus in Egypt was arrived at by virus isolations from man, birds and mosquitoes, by serologic studies in man, birds and other animals and by experimental infection of birds and other animals and of various arthropod species. The dominant cycle by which the virus is propagated is believed to be bird-mosquito-bird with *Culex univittatus* the principal vector. Some evidence was obtained that the virus may overwinter by means of a slow continuous cycle in which *Culex pipiens* is involved Human infection is widespread in those areas where mosquitoes prevail and occurs seasonally in relation to the presence of virus in mosquitoes. Although viremia in man may be sufficient to infect mosquitoes, it seems unlikely, in view of the high immunity rate in the population, that a man-mosquito cycle is of importance A wide range of other vertebrates is infected by the virus, but their infections are believed to be tangential or "dead-end."

Protection from, or control of, the vectors offers the only present approach to control of the disease.

ILHEUS VIRUS INFECTION

Ilheus virus has been found in South and Central America and in Trinidad, B.W I. It has been isolated from mosquitoes in Brazil, Honduras and Guatemala, and from both mosquitoes and man in Trinidad Serologic surveys indicate it to be a prevalent human infection in the Amazon valley in Brazil and in parts of Trinidad. This is not to imply that the virus does not occur elsewhere, but information is not available from other areas It seems probable that the virus is limited to the Western Hemisphere

milk from infected goats (Smorodintsev et al., 1954a). The resultant infection has been called biundulant meningo-encephalitis or diphasic milk fever by different workers; the nomenclature is further confused by the use of the former name for the clinically indistinguishable disease resulting directly from tick-bite. The clinical picture in man following infection with any of the above virus strains shows considerable variation from case to case, but, from strain to strain, the major difference seems to lie in the severity and the degree of CNS involvement, the louping-ill strain showing the lowest pathogenicity for man, and the Far Eastern Russian, the highest. An obvious analogy can be found in poliomyelitis with which, in fact, these infections are often confused.

At the present time two additional strains of the complex are known which cause a clinical picture quite at variance with the above in that CNS involvement apparently does not occur, but the systemic phase of the infection may be quite severe and accompanied by hemorrhagic manifestations. The first recognition of this type of disease was in the Omsk Oblast in Siberia in 1944-1946, hence it is known as Omsk hemorrhagic fever, and the causative virus was isolated in 1947 by an expedition of Soviet scientists under Chumakov (cf. Gajdusek, 1953). A somewhat similar disease has just been recognized and the virus isolated in Mysore state, India, by Work et al. (1957). It has been called Kyasanur forest disease and is believed to be of recent origin in the region, at least as the cause of serious or fatal infections in the human and monkey population. The relationship between the Siberian and Indian viruses and diseases has yet to be assessed.

Clinical Pictures

In the following discussion, aspects of the clinical pictures which are common to all strains are considered first. Subsequently, those infections which can lead to CNS involvement are discussed, and finally the hemorrhagic forms are described. The clinical pictures caused by the viruses of the Russian tick-borne complex are characteristically protean in nature, and the complex might be thought of as the prototype of all arbor viruses, since the diverse results of infection embody essentially all of those seen in one or another of the other arbor virus diseases. Infection may be inapparent, so mild as to escape diagnosis without laboratory aid, moderate to severe with or without permanent residua, or fatal. Onset of symptoms is abrupt, and a diphasic disease is probably characteristic, although one or the other phase may be absent or unrecognized. The first phase consists of a generalized systemic infection marked by fever, severe headache, malaise, generalized pains and gastro-intestinal manifestations. It has frequently been described as influenzalike. Signs of meningeal irritation may be observed but at this stage represent meningismus rather than true meningitis. The blood characteristically shows a leukopenia. The end of the first phase is marked by a fall in temperature and subsidence of symptoms. After a variable period, the onset of the second phase is marked by return of fever and with neurotropic strains, the development of signs of CNS involvement. The blood picture changes to show a moderate leukocytosis in infections involving the nervous system. This phase is comparable with clinically recognizable infection in St. Louis, Japanese B and other encephalitides. It must be emphasized that one or the other phase may not be noted.

Louping-ill infections in man may consist only of the first influenzalike phase or may have a diphasic course with a mild or severe meningo-encephalitis in the second phase. The diphasic picture is a feature of the disease in sheep. A favorable outcome without sequelae is to be expected and suggests that this strain has a decreased pathogenicity for man. The above account is based mainly on the reports of Edward (1948) and Lawson et al. (1949).

The tick-borne encephalitis now widely distributed throughout western Russia and Central Europe has been described under a variety of names by Soviet, Czechoslovakian, Yugoslavian and Austrian investigators (Silber and Soloviev, 1946; Smorodintsev et al., 1954a; Davidenkov et al., 1954; Rugevich et al., 1954; Chumakov, 1955; Hloucal and Gallia, 1949; Krejci, 1949; Bedjanič et al., 1955; Grinschgl, 1955). Among others, the names given have been western form of Russian tick-borne or spring-summer encephalitis, biundulant meningo-encephalitis, diphasic milk fever and Central European (or Czechoslo-

TABLE 13 GEOGRAPHIC DISTRIBUTION OF DISEASES CAUSED BY RUSSIAN TICK-BORNE COMPLEX

Area	Diseases
British Isles	Louping-ill, predominantly a disease of sheep
Soviet Union from the Far East to Western Russia in Europe	Russian tick-borne or spring-summer encephalitis Biundulant meningo-encephalitis or diphasic milk fever Omsk hemorrhagic fever
Central Europe, extending from Sweden and Finland in the north into the Balkan Peninsula in the south	Central European tick-borne virus encephalitis (Czechoslovakian, etc , tick-borne encephalitis)
India	Kyasanur forest disease
Malaya	Not known but virus isolated from ticks

mate clarification awaits the acquisition and exchange of more information by interested investigators throughout the world

The members of the complex have the common property of being transmitted by ticks of the family *Ixodidae* Mosquito transmission has never been demonstrated, and the available evidence indicates that they fail to multiply in such hosts However, the decision to consider all of the agents as strains of one virus rests on comparative antigenic analyses of all but one member of the complex. The missing member is the virus of Kyasanur forest disease, an entity isolated too recently to have allowed detailed study Although some antigenic differences are detectable, especially in detailed analysis by cross complement-fixation test, the overwhelming body of evidence indicates that no consistent distinction can be established among the strains by reciprocal neutralization tests and vaccination challenge experiments (Casals and Webster, 1944; Edward, 1950; Pond et al., 1953, Pond and Russ, 1955; Konowalchuk et al., 1957). Extensive comparative studies with convalescent human sera following natural infection have not been reported, although sera obtained from human beings vaccinated with a Russian spring-summer strain gave a similar degree of protection of mice against louping-ill, a Czechoslovakian strain and 4 Russian spring-summer strains (Pond et al, 1953) Since the experimental animal host seems to be unable to distinguish immunologically between the viruses, it seems reasonable to assume that man reacts in the same way, and on this basis the classification rests. It is probable that variations produced by different environmental conditions in nature influence the behavior of the individual strains, including their pathogenicity for man.

The present known distribution of the various diseases is given in Table 13.

In the British Isles, louping-ill has been known for over a century as a disease of sheep capable of producing CNS manifestations, the viral etiology was established in 1930 by Pool et al in Scotland It has never been a serious cause of human disease, most of the reported infections having occurred in laboratory workers, but a few natural infections have been described in persons working in close association with sheep in enzootic areas In the Soviet Union, the disease now known as Russian tick-borne or spring-summer encephalitis was first recognized as a clinical entity in the Far Eastern region by Panov in 1934, and Silber and his associates isolated the causative virus in 1937 However, Soviet scientists trace the disease back at least to 1880, when Kozhevnikov described a peculiar form of epilepsy now believed to be a sequel to tick-borne encephalitis Subsequent to the recognition of the disease in the Far East, it was also found to be present in Siberia and European Russia but in a generally less severe form, which led Soviet investigators to distinguish between the Far Eastern and Western varieties The disease now widespread in Central Europe appears to be indistinguishable from the Western variety. It is impossible to say how long the virus has been present in Central Europe, but recent reports suggest that it is becoming an increasingly important public health problem there Of considerable epidemiologic significance is the recognition by Soviet scientists that infection may be acquired by drinking

infection. Convalescence is prolonged in both, but there are no sequelae Kyasanur forest disease appears to be the more serious infection and more often fatal

Pathologic Picture

Detailed descriptions of the pathologic changes caused by neurotropic strains can be found in the review by Silber and Soloviev (1946) and the recent article by Grinschgl (1955). The chief distinction between the picture produced by the tick-borne complex and those of St Louis and Japanese B encephalitis is that the cervical cord is more often affected in the former In the individual case, poliomyelitis cannot be distinguished pathologically The leptomeninges are swollen, the brain is congested, and petechial hemorrhages are seen, especially in the brain stem, the medulla, and the horns of the spinal cord All stages of neuronal degeneration and necrosis are found, mainly in the gray matter, involving the anterior horns of the spinal cord, the medulla, the pons, the Purkinje cells of the cerebellum, and the cerebral motor cortex Extensive infiltrative and proliferative reactions occur Infiltration and degeneration of peripheral nerves, hyperplasia of the spleen and parenchymatous degeneration of the liver, the kidney and the myocardium have been reported

Detailed reports of pathologic findings in Omsk hemorrhagic fever are not available, but from the account of Gajdusek, gross hemorrhages in the gastro-intestinal tract and fine hemorrhages elsewhere are encountered The basic lesion is believed, by Soviet investigators, to involve the capillaries The pathologic picture in Kyasanur forest disease is based only on descriptions of 2 human cases by Work et al The main changes consisted of focal necrosis and bile stasis in the liver and acute tubular degeneration in the kidney The lungs showed patchy consolidation, and in one of the cases there was extensive oozing of blood into the lung in association with massive gastro-intestinal hemorrhage

Experimental Infection, Host Range

Of the common laboratory animals, the albino Swiss mouse is the most useful All of the strains are pathogenic for this animal by the intracerebral route on primary isolation with the exception of the virus of Omsk hemorrhagic fever. It is not clear whether the use of suckling mice might eliminate the need for adaptation passages with this strain. All of the strains, except for louping-ill, are also highly pathogenic for mice by other routes, although the intracerebral is preferable for most purposes The distinctive property, within Group B, of pathogenicity for adult mice on extraneural inoculation is useful in virus characterization Regardless of the strain used, the picture in the mouse is a fatal encephalomyelitis, the virus is present to high titer (10^{-8} to 10^{-9}) in the brain and can be maintained readily on serial passage

Strains of the complex with neurotropic potentialities for man characteristically produce encephalitis on intracerebral inoculation into rhesus monkeys, although a fatal outcome is not invariable Inoculation by peripheral routes may result in viremia and a silent, immunizing infection in the rhesus monkey but with one Russian strain, the cynomologus monkey was found to be more satisfactory for the production of consistent and sustained viremia It is suggested that this reaction provides a useful method for vaccine assay (Morris et al, 1955) The infection in this animal is otherwise silent, although encephalitis follows initial infection by the intracerebral route The virus of Omsk hemorrhagic fever produces a febrile reaction and immunity in the rhesus monkey following intraperitoneal inoculation, but no information is available as to results by other routes The high degree of pathogenicity of the Kyasanur forest disease virus for 2 species of Indian monkeys is indicated by the occurrence of epizootics among the langur (*Presbytis entellus*) and bonnet (*Macaca radiata*) monkeys in association with the human epidemics (Work et al, 1957)

The guinea pig may show a febrile reaction to various strains, and Soviet investigators report encephalitis in a small percentage of animals receiving neurotropic strains. It is not a satisfactory animal for virus propagation, although it provides a source of immune serum Some neurotropic strains are pathogenic for hamsters Rabbits are either insusceptible to infection with members of the complex or develop a silent infection with viremia of short duration

vakian, etc) tick-borne encephalitis. The incubation period is usually 7 to 10 days. The diphasic aspect of the infection is marked, although an unknown, probably large, number of cases never progress beyond the first nonspecific illness The duration of the first phase is from 5 to 10 days, and the afebrile period is usually 4 to 10 days Intense headache and high fever usher in the second phase, and the most frequent type of CNS involvement is serous meningitis of varying degree of severity Other CNS manifestations consist of spinal, bulbospinal and ascending types of paralyses and of encephalitis. The incidence of these complications varies considerably. The prognosis in those cases showing only meningitis or mild meningo-encephalitis is the most favorable Pareses or paralyses are generally of the flaccid type and may be transient or permanent. Death or permanent sequelae more commonly occur in those developing paralyses, and the gravest outlook is for those with the bulbospinal form Paralysis and atrophy of the muscles of the neck and the shoulders (shoulder-girdle paralysis) are not common Nystagmus, vertigo, somnolence and visual and mental disturbances indicate the development of encephalitis which, in severe cases, may go on to delirium or coma In all types of the disease, even in those without frank meningeal signs, the cerebrospinal fluid shows a moderate pleocytosis and increase in protein The usual duration of the second phase is 8 to 12 days

Convalescence is quite prolonged and marked by headache, debility and weakness Residual paralyses are the most common sequelae, but their incidence is not high According to Soviet sources, 3 to 5 per cent of the cases with paralyses show a progressive chronic course, including Kozhevnikov's epilepsy. The latter is characterized by constant clonic spasms of specific muscle groups which from time to time increase in intensity and develop into an epileptic seizure.

The first descriptions of serious human disease due to the viral complex were of the Russian Far Eastern form of encephalitis. The following is based mainly on the review by Silber and Soloviev (1946) The main differences between the preceding pictures and the Far Eastern variety are in the gravity of the latter disease and the absence of a diphasic course. Abortive and moderately severe cases were seen which showed serous meningitis with or without mild encephalitis, but many severe cases occurred in which the most characteristic finding was encephalitis accompanied by involvement of the cervical cord and bulbar centers. In such patients, the case fatality rate was high, and those surviving usually showed neck and shoulder-girdle paralysis of the flaccid type. Other permanent neurologic or psychotic sequelae without parkinsonism were seen, as were epileptiform seizures of the Kozhevnikov type. A convalescent period of several months was usual even for the uncomplicated case. It is not clear whether this severe form of the disease is still commonly found in parts of the Soviet Union, or whether this now represents the extreme disease picture with any of the neurotropic strains

Details concerning the two hemorrhagic forms of the infection are not yet available The following account is based on the review of Omsk hemorrhagic fever by Gajdusek (1953) and the preliminary report of Kyasanur forest disease by Work et al (1957) The two are considered together, although their relationship is not yet known. The incubation period in Kyasanur forest disease is 5 days or less, and both diseases frequently have a diphasic course, the second phase consisting of a return of fever and recurrence of previous symptoms without CNS involvement Both have a sudden onset with fever, headache and gastro-intestinal manifestations. Vomiting and diarrhea may be marked in the Indian disease Characteristic or even diagnostic of both is a hemorrhagic injection or enanthem of the palate. Generalized lymphadenopathy is common in both, and meningismus not uncommon, but true meningitis is absent Epistaxis, hematemesis and uterine bleeding are common but seldom profuse in Omsk hemorrhagic fever, while in the Kyasanur disease, epistaxis and severe gastro-intestinal hemorrhage occur in some cases. The latter disease may occur as a moderate or severe systemic disease without hemorrhagic manifestations Marked leukopenia and thrombocytopenia are seen in both, but the urine is normal in the Siberian disease and frequently shows albumin, casts and leukocytes during the febrile period of the Indian

the development of hemagglutination-inhibiting antibody following natural infection except for Kyasanur forest disease in which it has been observed to develop more rapidly than does the CF antibody (Work et al, 1957). Neutralizing antibody can be detected earlier than CF by use of the sensitive intraperitoneal technic, and in milder infections, a significant number of patients may fail to develop detectable CF antibody at any time (Smorodintsev et al, 1954a, Drobyshevskaya et al, 1954) Neutralizing antibody has been shown by Soviet investigators to persist for 20 years or more following infection with Russian strains, while CF antibody is of shorter duration

Diagnosis

A clinical diagnosis may be indicated by the following features of the diseases the sharply seasonal aspect in temperate climates, a history of contact with forested areas or of tick-bite, a history of drinking raw milk from goats, a diphasic disease course, the characteristic injection or enanthem on the palate in Omsk hemorrhagic fever and Kyasanur forest disease However, many other infections may be confused with these diseases, in particular, poliomyelitis with the severe CNS infections, other infectious hemorrhagic diseases in Siberia and bacterial enteritis in India Accurate diagnosis must rest on virus isolation or serologic study In infections with neurotropic strains, virus isolations have been made during the acute phase from blood and cerebrospinal fluid and from the brains of early fatal cases Numerous isolations have been made from blood early in the course of Omsk hemorrhagic fever and Kyasanur forest disease The technics have been mentioned in the section on St Louis and West Nile viruses Isolations of Omsk hemorrhagic fever virus were made in both guinea pigs and mice (Gajdusek, 1953), and Verlinde et al (1955) used the chick embryo inoculated on the chorio-allantoic membrane for some of the Austrian strain isolations

For serologic diagnosis, paired serum specimens are required as for St Louis virus The neutralization and complement-fixation tests have been used extensively for serologic diagnosis of all of these diseases In many areas where members of the complex occur there is no information to suggest that other members of Group B cause human infections, exceptions are India and the Far Eastern region of the Soviet Union Therefore, either neutralization or CF test usually give reliable results, although it should be kept in mind that Soviet investigators report a number of patients with relatively mild infections who failed to develop CF antibody In the Far Eastern Soviet Union, Japanese B infections also occur, but the serologic relationship between the two viruses is such that differentiation should be clear by one or the other test except in an individual previously infected with one and currently infected with the other, here a complex serologic response would be expected Results from the study of Kyasanur forest disease indicate that the CF test can provide a specific diagnosis but also suggests that other Group B infections occur in the same area leading to the diagnostic difficulties seen with multiple Group B infections (Kulkarni et al, 1958) HI antibody produced by this Indian strain is broadly cross-reactive within the group and is only of tentative diagnostic value The HI test should be of aid in the diagnosis of infections in Central Europe and most of the Soviet Union

Treatment

Treatment of any of the infections is symptomatic Some Soviet investigators appear to be convinced that convalescent human or hyperimmune horse or goat serum can have a beneficial effect if given early in infections with neurotropic strains (Chumakov, 1955) Hospital care is important for seriously ill patients as are measures to combat the effects of blood and fluid loss in the Omsk and Kyasanur forest diseases

Epidemiology

The capacity of strains of the complex to produce a high proportion of inapparent infections in man has been revealed by the demonstration of neutralizing antibody in a large part of the healthy population of endemic areas in the Soviet Union (Silber and Soloviev, 1946, Alekseyev and Gulamova, 1954) The sharply seasonal, spring-summer-autumn, character of outbreaks has been an aspect of all epidemiologic studies, the peak incidence in various areas depending on the seasonal activity of the vector tick species of

Sheep are susceptible to both louping-ill and Russian strains of the virus. Although slight differences in the clinical pictures have been described, both regularly produce a fatal encephalitis after intracerebral injection The louping-ill strain produces a variable picture from inapparent infection to fatal encephalitis following peripheral inoculation, but it is not clear that Russian strains have been shown to cause encephalitis by extraneural routes The preceding is based on reviews by van Rooyen and Rhodes (1948) and by Silber and Soloviev (1946).

Smorodintsev et al. (1954a) demonstrated the presence of virus in the milk of both naturally and experimentally infected goats and designated the relatively milder infections in man seen with this strain as biundulant meningo-encephalitis (diphasic milk fever). Recently, van Tongeren (1955-1956) has shown that the same phenomenon can be produced experimentally in goats with an Austrian strain capable of producing the most severe type of CNS damage in man The goat shows no marked reaction to infection but develops viremia and hemorrhages into the udder as indicated by the appearance of small amounts of blood in the infected milk

Infection of a large variety of other animals has been demonstrated with one or more members of the complex, many such infections are silent, but others lead to severe or fatal illness. In addition to sheep and goats, the results of studies of small mammals, especially forest rodents, and of wild birds are of particular significance Earlier investigations in the Soviet Union are reviewed by Silber and Soloviev (1946), and an important contribution has been made recently by Levkovich et al. (1955) who studied various animals and birds after experimental infection by tick bite or subcutaneous inoculation using a Russian strain They demonstrated sustained viremia in mice, voles, hedgehogs, ground squirrels, chipmunks and certain wild birds as well as in sheep and goats, hence, any or all of these animals are potential sources of vector infection and may act as disseminators of virus An Austrian strain has been shown to produce viremia lasting from 3 to 10 days in chickens, sparrows and rabbits (Pattyn and Wyler, 1955). A local muskrat species and two small field rodents have been found highly susceptible to the virus of Omsk hemorrhagic fever, and various other animals and wild birds develop a silent infection following experimental inoculation or tick bite.

Strains of the complex have been shown to grow in embryonated hens' eggs and to cause death of the embryos Verlinde et al (1955) described characteristic pocks after chorio-allantoic membrane inoculation of an Austrian strain Russian spring-summer and louping-ill strains grow in and destroy a variety of animal tumors in vivo without necessarily causing death of the host (cf Moore, 1954) Both these strains can be cultivated in the Maitland type of tissue culture and both show marked cytopathogenicity for HeLa cells in tissue culture (Oker-Blom, 1956, Moore, 1957) The Russian strain also grows in other cell lines, but complete cytopathogenicity was observed only with HeLa cells and a line of human adult fibroblasts (Moore, 1957). Similar information is lacking for other strains of the complex

Etiology

The immunologic basis for placing this virus complex in Group B has been discussed in Chapter 12, and justification for considering all members of the complex as strains of one virus is given above This position may be strengthened or altered as more information becomes available. The diameter of the Russian spring-summer and louping-ill strains is 15 to 25 mμ by gradocol membrane filtration. All strains have been shown to pass through Berkefeld V and N or Seitz filters Various strains have shown much the same properties as do the members of Group B discussed earlier, and the optimal conditions for preservation and experimental work are similar. Hemagglutinating antigens have been prepared with the Russian spring-summer and Kyasanur strains by acetone-ether extraction of suckling mouse brain or by protamine sulfate treatment of alkaline aqueous extracts of the same tissue (Casals and Brown, 1954; Kulkarni et al, 1958). Such hemagglutinins are most active with the red cells of the 1-day-old chick or the adult goose

Neutralizing and complement-fixing antibodies develop following infection with all strains. No information is available concerning

the development of hemagglutination-inhibiting antibody following natural infection except for Kyasanur forest disease in which it has been observed to develop more rapidly than does the CF antibody (Work et al., 1957). Neutralizing antibody can be detected earlier than CF by use of the sensitive intraperitoneal technic, and in milder infections, a significant number of patients may fail to develop detectable CF antibody at any time (Smorodintsev et al., 1954a, Drobyshevskaya et al., 1954). Neutralizing antibody has been shown by Soviet investigators to persist for 20 years or more following infection with Russian strains, while CF antibody is of shorter duration.

Diagnosis

A clinical diagnosis may be indicated by the following features of the diseases: the sharply seasonal aspect in temperate climates, a history of contact with forested areas or of tick-bite, a history of drinking raw milk from goats, a diphasic disease course, the characteristic injection or enanthem on the palate in Omsk hemorrhagic fever and Kyasanur forest disease. However, many other infections may be confused with these diseases; in particular, poliomyelitis with the severe CNS infections, other infectious hemorrhagic diseases in Siberia and bacterial enteritis in India. Accurate diagnosis must rest on virus isolation or serologic study. In infections with neurotropic strains, virus isolations have been made during the acute phase from blood and cerebrospinal fluid and from the brains of early fatal cases. Numerous isolations have been made from blood early in the course of Omsk hemorrhagic fever and Kyasanur forest disease. The technics have been mentioned in the section on St. Louis and West Nile viruses. Isolations of Omsk hemorrhagic fever virus were made in both guinea pigs and mice (Gajdusek, 1953), and Verlinde et al. (1955) used the chick embryo inoculated on the chorio-allantoic membrane for some of the Austrian strain isolations.

For serologic diagnosis, paired serum specimens are required as for St. Louis virus. The neutralization and complement-fixation tests have been used extensively for serologic diagnosis of all of these diseases. In many areas where members of the complex occur there is no information to suggest that other members of Group B cause human infections; exceptions are India and the Far Eastern region of the Soviet Union. Therefore, either neutralization or CF test usually give reliable results, although it should be kept in mind that Soviet investigators report a number of patients with relatively mild infections who failed to develop CF antibody. In the Far Eastern Soviet Union, Japanese B infections also occur, but the serologic relationship between the two viruses is such that differentiation should be clear by one or the other test except in an individual previously infected with one and currently infected with the other, here a complex serologic response would be expected. Results from the study of Kyasanur forest disease indicate that the CF test can provide a specific diagnosis but also suggests that other Group B infections occur in the same area leading to the diagnostic difficulties seen with multiple Group B infections (Kulkarni et al., 1958). HI antibody produced by this Indian strain is broadly cross-reactive within the group and is only of tentative diagnostic value. The HI test should be of aid in the diagnosis of infections in Central Europe and most of the Soviet Union.

Treatment

Treatment of any of the infections is symptomatic. Some Soviet investigators appear to be convinced that convalescent human or hyperimmune horse or goat serum can have a beneficial effect if given early in infections with neurotropic strains (Chumakov, 1955). Hospital care is important for seriously ill patients, as are measures to combat the effects of blood and fluid loss in the Omsk and Kyasanur forest diseases.

Epidemiology

The capacity of strains of the complex to produce a high proportion of inapparent infections in man has been revealed by the demonstration of neutralizing antibody in a large part of the healthy population of endemic areas in the Soviet Union (Silber and Soloviev, 1946, Alekseyev and Gulamova, 1954). The sharply seasonal, spring-summer-autumn, character of outbreaks has been an aspect of all epidemiologic studies, the peak incidence in various areas depending on the seasonal activity of the vector tick species of

the areas The geographic distribution of the various diseases is given above (Table 13), and it is clear that one or more members of the complex are known to be present over an extremely wide area of Europe and Asia. The first epidemic recognized in central Europe was in Czechoslovakia in 1948 (Hloucal and Gallia, 1949). Subsequently, similar outbreaks were reported from Yugoslavia, Austria and Poland (Kmet et al., 1955; Richling, 1955, Przesmycki et al, 1956). New foci of Omsk hemorrhagic fever were recognized recently, although it is not known as an entity outside of western Siberia (Gagarina and Netskii, 1955) Antibody to the complex was found in a few individuals in India well before the recent outbreaks of Kyasanur forest disease (Smithburn et al, 1954a), and there is suggestive evidence for the occurrence of antibody in man in Malaya where a strain of the complex has been isolated from ticks (Smith, 1956)

Since these diseases are believed to result directly or indirectly from infected tick bites, they are rural rather than urban in distribution, and the case distribution according to age, sex and occupation is determined by the closeness of contact with sources of infection, in particular, with forested areas Thus, a high proportion of infections is usually seen in young adult male agricultural and forest workers, although cases have occurred among urban dwellers of all ages and either sex following visits to rural areas, and milk-borne infections have a familial or group aspect Infection with the louping-ill strain may be acquired as a result of handling tick-infested sheep and has been seen in abattoir workers

Statistics as to case fatality rates are extremely variable. The highest figure, 29 per cent, is given for the early epidemics in the Far Eastern Soviet Union Subsequent outbreaks in Western Russia and Central Europe have been associated with rates from 0 to 14 per cent No fatal human infections with the louping-ill strain have been reported The over-all mortality from Omsk hemorrhagic fever is given as 1 to 2 per cent, while preliminary reports from India suggest that in Kyasanur forest disease, the rate may be as high as 28 per cent The explanation for these differences is unknown, but they suggest a considerable degree of variation in pathogenicity for man from strain to strain.

In the Soviet Union, the two major tick vectors of the neurotropic virus strains are *Ixodes persulcatus* and *I. ricinus* *I. persulcatus* tends to be an eastern species and *I. ricinus* a western, but the distribution of the two overlaps, and where this occurs the seasonal incidence of disease may be prolonged due to differences in seasonal activity of the tick species. Repeated virus isolations have been made from naturally infected ticks of both species (Silber and Soloviev, 1946; Smorodintsev et al., 1954a). *I. ricinus* is the only vector implicated elsewhere in Europe, and virus has been isolated from wild-caught ticks of this species in Czechoslovakia, Hungary, Yugoslavia, Poland and Austria (Rampas and Gallia, 1949; Fornosi and Molnár, 1954, Likar and Kmet, 1956; Przesmycki et al., 1956, Jettmar, 1956). Both *Dermacentor pictus* and *D marginatus* have been found infected with Omsk hemorrhagic fever virus (Gajdusek, 1953, Gagarina and Netskii, 1955) and in India, Kyasanur forest disease virus has been recovered repeatedly from wild-caught *Haemaphysalis* ticks, the species so far identified being *H spinigera* (Work and Trapido, personal communication). The strain of the complex isolated in Malaya was obtained from *Ixodes granulatus*. Transmission of infection to experimental animals has been demonstrated with the louping-ill strain by *I. ricinus*, with Russian spring-summer strains by *I persulcatus* and *I. ricinus* and with Omsk hemorrhagic fever by *D pictus*. Unlike the purely vector role of the mosquito in other virus infections, the tick can be both vector and reservoir, for in studies carried out with Russian strains, it has been found to remain infective for long periods of time and to transmit virus transovarially through successive generations (Silber and Soloviev, 1946). Transovarial transmission has also been demonstrated with Omsk hemorrhagic fever in *D. pictus* (Gajdusek, 1953) The tick acts as the indirect vector in the milk-borne infections recently recognized by Soviet investigators (Smorodintsev et al, 1954a) So far, such infections have been related only to the ingestion of raw milk from goats infested with ticks in pasture It is believed that a similar

epidemiologic picture occurs in Austria (van Tongeren et al., 1955-1956)

Certain small mammals, in particular rodents, and some wild birds have been implicated in the epidemiologic cycle of these viruses by virus isolation, demonstration of antibody or both. In early studies, such vertebrates were considered to be the reservoirs, but more recently they have come to be looked upon rather as virus disseminators which serve to increase the density of tick infection in a given area and spread it into more distant ones. In the Soviet Union, virus or antibody has been found in squirrels, chipmunks, hares, field and forest mice, wild rats, voles, hamsters, hedgehogs, porcupines, moles, grouse and various Passerine birds (Chumakov et al., 1940, Pavlovsky, 1941, Silber and Soloviev, 1946; Warren, 1946). Antibody has been found in wild rodents in Malaya (Smith, 1956) and in India (Work and Trapido, personal communication). Many of the same animals and birds show sustained viremia after experimental infection.

The importance of sheep and goats in certain of these diseases has been discussed. Cattle and horses apparently experience immunizing infections but have not been implicated otherwise.

CONTROL

A formolized mouse brain vaccine has been used in the Soviet Union for some years and has given favorable results in a number of field studies (Warren, 1946. Gajdusek, 1953). A similar vaccine prepared from sheep cord and brain has been successful in protecting sheep from louping-ill infection (van Rooyen and Rhodes, 1948). Soviet workers also recommend immune serum prophylaxis for nonimmune individuals following tick-bite in endemic areas or laboratory exposure. The use of protective clothing and insect repellents and, where feasible, local tick and rodent control measures are advocated. According to Soviet sources, one acaricide aerosol bomb can exterminate most of the ticks in 5 to 7½ acres of forest and inhibit tick repopulation for a period of at least 5 to 7 days (Chumakov, 1955). Control of tick infestation of sheep by dipping can be used in the prevention of louping-ill infections. Goats' milk should be boiled where milk-borne infection is suspected.

UGANDA S VIRUS

Uganda S virus was isolated from *Aëdes* mosquitoes in Uganda by Dick and Haddow (1952). Subsequently, another strain of the virus was isolated by Ross (1956) and characterized as identical with Uganda S by Spence and Thomas (1958). This strain was isolated from mosquitoes in Tanganyika and designated Makonde virus. Uganda S virus has not been associated with overt human disease, although neutralizing antibodies have been demonstrated in the sera of human beings in various areas.

The virus multiplies in *Aëdes aegypti* mosquitoes infected by inoculation (Whitman, personal communication). It is highly pathogenic for the albino Swiss mouse in which it produces a lethal infection by the intracerebral route in adult animals and by both intracerebral and intraperitoneal routes in suckling mice. It is readily maintained by serial passage in mice and attains a brain titer of 10^{-7} to 10^{-8}. It shows little or no pathogenicity for other common laboratory animals including the embryonated egg, although it multiplies in the latter host (Taylor, 1952). Tissue culture studies have shown poor multiplication and cytopathogenicity in various cell lines (Moore, 1957). The virus is of the same size (15 to 22 mμ) as other Group B viruses (Smithburn and Bugher, 1953), and the optimal conditions for storage and experimental work are the same. Studies carried out by Kerr (1952) and by MacNamara (1953b) have shown a close immunologic relationship between Uganda S and yellow fever viruses demonstrable both by complement-fixation and neutralization tests. In the latter, the relationship tends to be more marked when yellow fever immune serum is tested against Uganda S virus. A hemagglutinin was demonstrated in acetone-ether extracted suckling mouse brain by Casals and Brown (1954).

Neutralization of the virus has been observed with human sera obtained in various parts of the world. A significant incidence of neutralizing antibodies has been found in Uganda, Tanganyika, India, Malaya and

must be interpreted with caution, since when comparative studies were done, the same sera were usually shown to neutralize at least one other Group B virus, and MacNamara showed that convalescent sera from proved cases of yellow fever neutralized Uganda S virus It has not been determined unequivocally that this virus can cause human infection, although a closely related but not identical virus has been isolated from the blood of a febrile child in Natal, South Africa (South African Institute for Medical Research, 1956)

ZIKA VIRUS INFECTION

Zika virus was isolated by Dick et al (1952) from the blood of a febrile sentinal monkey in a forest in Uganda and later from wild-caught *Aedes africanus* mosquitoes in the same forest. It was subsequently isolated from the blood of a febrile patient in Nigeria by MacNamara (1954) The virus has been shown to be capable of producing a clinically demonstrable infection in man in 3 cases studied by MacNamara and in the experimentally induced infection reported by Bearcroft (1956). The infection in man is associated with fever, headache and malaise, and possibly jaundice in some, although the last may have arisen from concomittant infection with another agent

The virus is readily maintained by serial passage in the albino Swiss mouse in which it produces a fatal infection and brain titers of around 10^{-7} following intracerebral inoculation. The suckling mouse is highly susceptible to infection by the intraperitoneal route Guinea pigs and rabbits show no visible reaction to infection, although they may be immunized, and a nonfatal infection is likewise produced in the chick embryo (Taylor, 1952) Monkeys develop inapparent infections characterized by moderately sustained viremia and the subsequent development of antibody. The virus multiplies in various cell lines in tissue culture and shows marked cytopathogenicity for HeLa cells and human adult fibroblasts (Moore, 1957) It has physical properties similar to related viruses, including [illegible]

The basis for placing the virus in Group B has been discussed in Chapter 12, and detailed analysis by cross-complement-fixation tests has shown a slightly closer relationship to yellow fever virus than to other members of the group, although this is not supported by HI or neutralization test (Casals, personal communication). The observation that a rise in yellow fever antibodies occurs in a yellow-fever-immune human being or animal following infection with Zika virus (Bearcroft, 1956) is to be expected following superinfection with any Group B virus

Experimental transmission of the virus by *Aëdes aegypti* mosquitoes was demonstrated by Boorman and Porterfield (1956). Neutralization of the virus by the serum of human inhabitants of Uganda and Tanganyika was demonstrated in 6 to 13 per cent of those tested (Dick et al, 1952; Smithburn, 1952) In India, Malaya and Borneo, 17 to 19 per cent neutralization rates were found (Smithburn et al, 1954a, Smithburn, 1954) As in the case of Uganda S, however, there was a strong tendency for the same sera to neutralize other Group B viruses Therefore, such results are difficult to assess.

NTAYA VIRUS

Ntaya virus was isolated by Smithburn and Haddow (1951) from a mixed lot of wild-caught mosquitoes in Uganda So far, a subsequent isolation has not been reported The virus has been shown to multiply in *Aëdes aegypti* mosquitoes infected by inoculation (Whitman, personal communication). It is pathogenic for albino Swiss mice by the intracerebral route and reaches after adaptation a titer of about 10^{-6} in mouse brain. It is not pathogenic for rhesus monkeys and apparently fails to multiply in them, since repeated large inocula are required to produce demonstrable antibodies It produces a fatal infection in chick embryos following inoculation by the yolk and amniotic sac routes (Taylor, 1952) Some degree of virus multiplication has been observed in various cell lines in tissue culture, but cytopathogenicity was marked only for human adult fibroblasts (Moore, 1957) The size as determined by gradocol membrane

filtration has been reported as 80 to 122 mμ (Smithburn and Bugher, 1953), which is much larger than any other member of Group B so far studied A hemagglutinin is demonstrable in suckling mouse brain (Casals and Brown, 1954)

Antibodies neutralizing Ntaya virus have been found in the sera of residents of various parts of the world, and frequently the incidence of such antibodies has been quite high In Egypt, for example, an over-all rate of 34 9 per cent was found (Smithburn et al, 1954b) The extensive virologic studies carried out in Egypt by Taylor and his associates (1956) failed to result in a single isolation of Ntaya virus One striking aspect of all recent surveys has been that Ntaya-positive sera in almost all cases also neutralize at least one other Group B virus; the positive sera in Egypt are associated with West Nile virus neutralization. The capacity to neutralize Ntaya has been demonstrated to develop in convalescent sera from known West Nile infections In other parts of the world, a similar association is found with dengue and Japanese B antibodies where these represent the prevalent infections It seems extremely doubtful, therefore, that Ntaya virus has been demonstrated to infect man, a resonable explanation of the high incidence of neutralization is that the antigenic structure of Ntaya virus is such as to render it particularly susceptible to the action of various Group B antibodies

WESSELSBRON VIRUS INFECTION

Wesselsbron virus was first described by Weiss, Haig and Alexander (1956) who isolated it from a dead lamb in the Orange Free State in South Africa Shortly after the original isolation, two additional strains were obtained in Natal, South Africa, by Smithburn et al (1957), one from human blood and one from mosquitoes

The virus is the cause of abortion and death in pregnant sheep and of death in newborn lambs It is not yet known whether it has a similar effect in other domestic animals, nor has it been determined how serious a cause of economic loss this infection may be The virus causes an influenzalike febrile disease in man in which a rash may be seen and from which convalescence may be somewhat prolonged Knowledge of the human infection is based on 1 naturally and 4 laboratory acquired infections.

Degenerative changes are seen in the liver *of pregnant ewes and lambs dying from the* disease, and virus can be isolated from liver and brain of dead lambs. Infection of pregnant guinea pigs and rabbits also results in abortion or neonatal death of the young Thus, the virus appears to be pantropic with a predilection for embryonic mammalian tissue Early studies showed a low mortality but a high morbidity rate among nonpregnant adult sheep, nonpregnant cattle, horses and pigs experience a mild febrile immunizing infection Nonpregnant guinea pigs, rabbits and *Cercopithecus* monkeys show symptomless infection but may be immunized As with many other Group B viruses, adult mice succumb to infection by the intracerebral route, and suckling mice by both the intracerebral and the intraperitoneal routes The virus attains a brain titer in mice of around $10^{-7.6}$. The embryonated egg is a good host for virus multiplication, but deaths are inconstant and irregular The size of the virus as determined by Polson is approximately 30 mμ (Weiss et al, 1956). Casals (1957) demonstrated a hemagglutinin in suckling mouse brain and classified the virus as a member of Group B (virus designated SA H177 in reference)

The virus has been isolated from naturally infected *Aedes circumluteolus*, *Aedes caballus*, and *Taeniorhynchus uniformis* mosquitoes in South Africa and experimental transmission accomplished with the first 2 species (Muspratt et al, 1957; Smithburn, personal communication). Virus has been isolated from animals or mosquitoes in rather widely separated areas of the Union of South Africa, including the Orange Free State, Northeastern

ease in sheep (Smithburn, personal communication) A high incidence of antibody has been found in domestic animals over a wide area of South Africa and in human beings in Northeastern Natal, the only area so far

studied (Weiss et al., 1956; Smithburn et al, 1957) It is too early to know whether this newly recognized disease occurs in other parts of the world.

BAT SALIVARY GLAND VIRUS

Burns and his associates first reported the isolation of a virus from the salivary glands *of Mexican free-tailed bats* in Texas (Burns and Farinacci, 1956; Burns et al., 1957) An apparently identical virus has been isolated repeatedly from the same species of bat in California (Johnson, unpublished results) The virus is pathogenic for mice by the intracerebral route and also produces a lethal encephalitis when inoculated into Mexican *free-tailed bats by the same route* It is not pathogenic for several other common laboratory animals, including chick embryos, but multiplies in the latter Although virus can be isolated from the brains of intracerebrally inoculated bats, it has not been recovered from the brains, the spleens or the hearts of the animals found infected in nature A hemagglutinin has been demonstrated and the virus has been placed in the arthropod-borne Group B by virtue of its immunologic relationship to St Louis, Japanese B, Murray Valley, West Nile and Ntaya viruses (Burns et al, 1957) It is of interest that it fails to multiply when inoculated into mosquitoes of 3 different genera *Anopheles quadrimaculatus, Culex fatigans* and *Aedes aegypti* (Whitman, personal communication) Its significance is unknown beyond the fact that it represents the second member of Group B demonstrated within the United States.

SPONDWENI VIRUS

Spondweni virus was isolated recently from *Taeniorhynchus uniformis* mosquitoes in northern Natal, South Africa, by Kokernot et al (1957) It is pathogenic for mice by the intracerebral route but not for several other species of laboratory animals A hemagglutinin has been demonstrated and the virus classified by serologic methods as a member of Group B. Preliminary results indicate that antibody capable *of neutralizing the virus can* be detected in the sera of some human residents of an area near that yielding the in*fected mosquitoes.*

Yellow Fever

(SYNONYMS *Fièvre jaune, fiebre amarilla, febre amarela, Gelbfieber*)

INTRODUCTION

Yellow fever in man is an acute infection caused by a virus The causative agent belongs to Casals' Group B (Chap 12) and is immunologically related to dengue, Uganda S, Zika, Ilheus, etc. In severe cases, yellow fever is characterized by an incubation period of from 3 to 6 days, fever, a pulse rate relatively slow in proportion to the temperature, albuminuria, jaundice, and a tendency to hemorrhage, particularly from the mucosa of the stomach and the gums Clinically, the disease varies from an almost symptomless infection to a severe, rapidly fatal one, death occurring usually within 10 days of onset There are no sequelae, and recovery leaves a lifelong immunity Man acquires the infection by the bite of an infected mosquito The disease occurs in 2 main epidemiologic types In the first, the virus is transmitted from man to man by certain species of mosquito belonging to the genus *Aëdes* of domestic or semidomestic nature The classic urban yellow fever belongs to this type, the virus cycle being man—*Aëdes aegypti*—man In the second, man is only incidentally infected in the course of a virus cycle involving wild animals, particularly monkeys and forest-loving mosquitoes Yellow fever is now endemic in large areas of continental tropical South America and Africa

HISTORY

It is not known whether the original home of yellow fever was in Africa or in America The first epidemic that can be definitely identified as yellow fever occurred in Yucatan in 1648 (Carter, 1931), accounts of previous epidemics are too vague for identification, but there can be little doubt that at this time the disease was very widespread During the 17th, the 18th and the 19th centuries, the disease was widely distributed throughout the Caribbean islands and the adjoining coastal regions of North, Central and South America From this large focus, at times it was transported to more northerly located cities Baltimore, Philadelphia and New York sometimes suffered severe epidemics, which were always confined to the warmer months of the year, disappearing entirely with the onset of cold weather and leaving the cities free until reinfected from outside During this era, yellow fever was essentially a disease of the trade routes of the Atlantic Epidemics were common on sailing vessels where *A aegypti* bred in water vats, and this means of transportation was undoubtedly the method of dissemination On several occasions, yellow fever was taken into the Iberian peninsula where severe epidemics occurred From infected coastal towns, yellow fever was introduced into the heart of North and South America by traffic on the Mississippi and the Amazon.

Some evidence of the severity of yellow fever may be obtained from the figures quoted

of the use of human volunteers (Reed et al, 1911) Of 22 cases produced by the bite of from 1 to 15 infected *Aëdes aegypti* mosquitoes, the mean incubation period was 3 days and 17 hours The extremes were 2 hours less than 3 days, and 2 hours more than 6 days However, the incubation period of yellow fever, acquired from accidental laboratory infection may be 10 days

A patient with a typical infection becomes ill suddenly The clinical course of a severe case is usually divided into the stages of active congestion and stasis with the following signs and symptoms The onset is usually acute and marked by fever, rigor, headache and backache The temperature rises rapidly to reach its maximum on the first or second day. The initial temperature is continuous and seldom exceeds 103 5° F The period of active congestion lasts 3 or 4 days, then the temperature drops The stage of stasis then sets in, and the temperature rises again but seldom reaches its previous maximum The two stages may coalesce without any drop in temperature to mark the transition During the stage of congestion the patient is intensely ill and restless, nausea and vomiting are common. The face is flushed, lips swollen, and eyes injected. The tongue is bright red A tendency to bleeding may be apparent early During the stage of stasis the whole aspect changes The active congestion fades, to be replaced by a venous stasis The face is no longer swollen, and a dusky pallor replaces the bright red of the first stage The gums become swollen and spongy and bleed spontaneously or on light pressure Nausea and vomiting are common The vomited matter usually contains some altered blood, this is the "black vomit" The tendency to hemorrhage is marked, ecchymoses may develop, melena is common The pulse rate is markedly slow in relation to the temperature, this is known as Faget's sign and develops during the first stage, becoming progressively more marked during the second stage The blood pressure is low Albuminuria usually appears toward the end of the period of congestion but becomes very marked during the period of stasis Oliguria or anuria may develop Jaundice appears during the second stage and is seldom very marked, indeed, it may be absent It is more marked as a rule in cases in which the malady is prolonged and in convalescence. Most deaths occur on the sixth or seventh day and seldom later than 10 days after onset. Complications are not frequent Recovery is rapid and complete.

The severity of the disease varies from an extremely mild to a fulminating infection It is possible that many immunizing infections are without symptoms Diagnosis can then be made only by serologic tests However, a study of yellow fever accidentally contracted in the laboratory (Berry and Kitchen, 1931) demonstrated that mild cases show many of the characteristic signs and symptoms of the severe ones In all but a few cases, the saddleback type of temperature curve is apparent The pulse reaction is typical, the peculiar relationship of a slowing heartbeat in a constant or increasing temperature is almost invariable Albuminuria, such a marked feature in severe cases, may be entirely absent in mild ones An important sign in yellow fever infection is the change observed in the white blood cell count There is a steady fall in the number of leukocytes, beginning with the onset of the disease The leukopenia is at its maximum on the fifth or sixth day and is chiefly due to a decrease in the number of neutrophils Lymphopenia is usual and may be marked (Berry and Kitchen, 1931)

The most marked pathologic changes in yellow fever are observed in the liver and the kidneys In the most severe cases there is an almost complete destruction of the parenchymatous cells of the liver, consequently, one finds the metabolic changes associated with extensive liver destruction There is a prothrombin deficiency commensurate with the amount of liver damage This deficiency is probably the cause of the marked hemorrhagic diathesis observed in yellow fever. The bilirubin content of the serum in severe cases is increased According to Elton et al (1955), the kidney lesion is a lower nephron nephrosis resulting from the hemorrhagic diathesis The development of this nephrosis is indicated by the extreme retension of nonprotein nitrogenous metabolites, particularly urea, and may be severe enough to cause death from uremia

Most authorities agree that in the African, yellow fever is as a rule milder than in other races It is possible that this mildness is due not to genetic factors but to a partial im-

by Reed et al. (1911) It was estimated that there must have been at least 500,000 cases of the disease in the United States during the period between 1793 and 1900. The great epidemic in Spain in 1800 caused 60,000 deaths In Rio de Janeiro, yellow fever was responsible for 23,000 deaths between 1851 and 1883. It was first reported in Cuba in 1640 and was almost continuously present until 1900, causing 35,900 deaths in Havana during the period between 1853 and 1900. During the brief occupation of Cuba by the American forces at the time of the Spanish-American War, 1,575 cases of yellow fever with 231 deaths occurred in the American army, because of this the Yellow Fever Commission was appointed, with Major Walter Reed in charge Modern knowledge of the etiology and the epidemiology of yellow fever stems from the findings of this commission, which clearly demonstrated that the agent responsible for yellow fever passed through bacteria-tight filters, was present in the blood of a patient during the first 3 days of fever, and that the mosquito *Aedes aegypti* was capable of transmitting the disease by bite, provided that a period of 12 days was allowed to lapse after an infective feeding Acting on this information, Gorgas, by applying anti-mosquito measures, was able to eradicate yellow fever from Havana

Following the application of anti-aegypti measures, it was noticed that yellow fever showed a tendency to disappear from neighboring small towns and villages This led to the development by Carter of the "key center" theory, according to which, two factors are necessary to maintain yellow fever in a community (1) a large population of susceptible human beings and (2) a constant supply of the mosquito As considerable evidence was available that an attack of yellow fever produced a lifelong immunity, it was obvious that the requisite number of susceptible persons could occur only where an adequate immigration of people from yellow-fever-free countries took place or in large cities where the newborn supplied this factor On the basis of this theory, the possible key centers were surveyed, and a campaign was set on foot with the object of eradicating yellow fever from the Americas One of the major key centers was Guayaquil Following the eradication of yellow fever from this city the disease disappeared from the entire Pacific coast of South America At the time when it looked as though this campaign was about to be crowned with success a sudden and unexplained epidemic of yellow fever occurred in Rio de Janeiro in 1928.

Stokes et al. (1928), investigating yellow fever in Africa, showed that the rhesus monkey is susceptible to the virus By the use of this experimental animal, it was shown that monkeys indigenous to Africa or South America are susceptible to yellow fever and that mosquitoes, other than *Aëdes aegypti*, under experimental conditions can transmit the virus. These observations first opened up the possibilities of an epidemiology of yellow fever not confined to the cycle, man-*aegypti*-man This possibility was emphasized by the finding of cases of yellow fever in South America in areas where *Aedes aegypti* does not exist and led to the discovery of the epidemiologic entity now known as jungle yellow fever. It has been clearly established that yellow fever virus is maintained in the jungle in South America and Africa in the absence of both man and *A aegypti* and that under such conditions man becomes infected only by close contact with the jungle

The discovery (Theiler, 1930) that white mice are susceptible to an intracerebral inoculation of yellow fever virus, even though the experimental disease in this host does not show the clinical and pathologic pictures of the human malady, led to the development of various protection tests which have proved to be valuable in the study of the epidemiology and the distribution of the disease. The observation that serial passage of the virus in the brains of mice produces a loss of virulence for monkeys led to one method of human vaccination which is still used extensively A more profound modification of the virus was produced by its prolonged maintenance in tissue culture This led to the development of the 17D strain of virus, which is likewise still in use for human vaccination

CLINICAL PICTURE

The most exact information available concerning the incubation period of infection with yellow fever is that obtained as a result

of the use of human volunteers (Reed et al., 1911) Of 22 cases produced by the bite of from 1 to 15 infected *Aedes aegypti* mosquitoes, the mean incubation period was 3 days and 17 hours The extremes were 2 hours less than 3 days, and 2 hours more than 6 days However, the incubation period of yellow fever, acquired from accidental laboratory infection may be 10 days.

A patient with a typical infection becomes ill suddenly. The clinical course of a severe case is usually divided into the stages of active congestion and stasis with the following signs and symptoms The onset is usually acute and marked by fever, rigor, headache and backache The temperature rises rapidly to reach its maximum on the first or second day The initial temperature is continuous and seldom exceeds 103 5° F The period of active congestion lasts 3 or 4 days, then the temperature drops The stage of stasis then sets in, and the temperature rises again but seldom reaches its previous maximum The two stages may coalesce without any drop in temperature to mark the transition During the stage of congestion the patient is intensely ill and restless; nausea and vomiting are common The face is flushed, lips swollen, and eyes injected The tongue is bright red A tendency to bleeding may be apparent early During the stage of stasis the whole aspect changes The active congestion fades, to be replaced by a venous stasis The face is no longer swollen, and a dusky pallor replaces the bright red of the first stage The gums become swollen and spongy and bleed spontaneously or on light pressure Nausea and vomiting are common The vomited matter usually contains some altered blood, this is the "black vomit" The tendency to hemorrhage is marked, ecchymoses may develop, melena is common The pulse rate is markedly slow in relation to the temperature, this is known as Faget's sign and develops during the first stage, becoming progressively more marked during the second stage The blood pressure is low Albuminuria usually appears toward the end of the period of congestion but becomes very marked during the period of stasis Oliguria or anuria may develop. Jaundice appears during the second stage and is seldom very marked; indeed, it may be absent It is more marked as a rule in cases in which the malady is prolonged and in convalescence Most deaths occur on the sixth or seventh day and seldom later than 10 days after onset. Complications are not frequent Recovery is rapid and complete.

The severity of the disease varies from an extremely mild to a fulminating infection It is possible that many immunizing infections are without symptoms Diagnosis can then be made only by serologic tests. However, a study of yellow fever accidentally contracted in the laboratory (Berry and Kitchen, 1931) demonstrated that mild cases show many of the characteristic signs and symptoms of the severe ones. In all but a few cases, the saddleback type of temperature curve is apparent The pulse reaction is typical; the peculiar relationship of a slowing heartbeat to a constant or increasing temperature is almost invariable Albuminuria, such a marked feature in severe cases, may be entirely absent in mild ones An important sign in yellow fever infection is the change observed in the white blood cell count There is a steady fall in the number of leukocytes, beginning with the onset of the disease. The leukopenia is at its maximum on the fifth or sixth day and is chiefly due to a decrease in the number of neutrophils Lymphopenia is usual and may be marked (Berry and Kitchen, 1931)

The most marked pathologic changes in yellow fever are observed in the liver and the kidneys In the most severe cases there is an almost complete destruction of the parenchymatous cells of the liver, consequently, one finds the metabolic changes associated with extensive liver destruction There is a prothrombin deficiency commensurate with the amount of liver damage This deficiency is probably the cause of the marked hemorrhagic diathesis observed in yellow fever The bilirubin content of the serum in severe cases is increased According to Elton et al (1955), the kidney lesion is a lower nephron nephrosis resulting from the hemorrhagic diathesis The development of this nephrosis is indicated by the extreme retension of nonprotein nitrogenous metabolites, particularly urea, and may be severe enough to cause death from uremia

Most authorities agree that in the African, yellow fever is as a rule milder than in other races It is possible that this mildness is due not to genetic factors but to a partial im-

munity produced by previous infection with another virus belonging to Group B. However, among Africans, severe epidemics with a number of deaths, such as that which occurred in the Nuba Mountains in Africa, have been reported (Kirk, 1941) Opinions differ as to whether the disease in children is as severe as in adults It is very difficult to evaluate the over-all mortality of yellow fever. This is usually high in cases in which black vomit and jaundice occur. However, experience has shown that for every case diagnosed, there are usually a great many undiagnosed mild infections as shown by the development of specific neutralizing antibodies Taking into account missed cases, the mortality is probably seldom greater than 5 per cent.

PATHOLOGIC PICTURE

The outstanding macroscopic findings in yellow fever are signs of degeneration in the liver, the kidney and the heart, accompanied by hemorrhages and jaundice The cadaver usually has a livid appearance, due to venous congestion Since the blood in fatal yellow fever remains fluid for a long time, it collects in the dependent portions of the body. Jaundice is always present, seldom well marked The liver is of normal size or slightly enlarged, somewhat yellow in color, and fatty on section, when drained of blood, it has a boxwood color The tense and swollen kidneys are likewise fatty and yellow; the cortex is not clearly demarcated from the medulla Evidence of hemorrhage is usually found, the most frequent site is in the mucosa at the pyloric end of the stomach, where erosions and punctate hemorrhages are present. In very few cases is there a complete absence of altered blood in the stomach contents.

On microscopic examination, the most characteristic lesions are found in the liver (da Rocha Lima, 1912). The liver cells undergo cloudy and fatty degeneration and a distinctive type of necrosis The necrotic cells are mainly confined to the midzone, although in severe cases the necrosis may involve almost the entire lobule. In such cases, however, there will always be found a few normal-appearing cells about the central vein and about the periphery of the lobule. Furthermore, all cells in the midzonal section may not be destroyed, resulting in a spotty distribution of the necrotic areas. The necrosis is hyaline in type and may be confined to part of the cytoplasm, but usually the whole cell is involved. Such necrotic, hyaline cells are known as Councilman bodies. The Kupffer cells are enlarged and may be granular in appearance The sinusoids in the necrotic areas are engorged Actual hemorrhage in the liver is rare In spite of extensive necrosis, the architecture remains intact. During recovery the parenchymatous cells are replaced, leading to a complete restoration of the liver without residual signs of infection such as cirrhosis

The lesions observed in the kidney are not distinctive. As in the liver, there is a complete absence of inflammatory reaction Cloudy and fatty degeneration of the entire kidney tubule, often more marked in the convoluted portion, is usually present The spleen is usually hyperemic, but this is unaccompanied by a leukocytic infiltration (Klotz and Belt, 1930). The most distinctive feature is found in the malpighian corpuscles At first there is a mononucleosis consisting of undifferentiated cells derived from the reticular tissue which persists throughout the entire course of the disease There is a striking loss of lymphocytes False germinal centers are formed. Degeneration is marked throughout the entire organ, which, characterized by cells with vesicular nuclei and waxy-appearing cytoplasm, may lead to actual necrosis, particularly noticeable in the false germinal centers Parallel changes are observed in the lymph nodes Degenerative changes are present throughout the heart

Lesions observed in rhesus monkeys are essentially the same as those in man, namely, degenerative lesions in the liver, the kidney, the spleen and lymph nodes In monkeys that have died of yellow fever following inoculation of unmodified virus, there are no lesions of encephalitis. The encephalitis produced by the neurotropic virus presents no distinctive features, being manifested by necrosis of ganglion cells and perivascular infiltration with round cells. Similar changes are found in the central nervous system of infected mice.

Yellow fever virus infection may produce inclusion bodies, which are intranuclear, acidophilic, variable in size, granular in appearance and irregular in outline. As a rule, they partially surround the nucleolus The

chromatin of the nucleus becomes marginated. These bodies are seen only occasionally in livers of human beings with yellow fever (Cowdry and Kitchen, 1930) The inclusions are found in the nuclei of parenchymatous cells of the liver of infected monkeys and in cells of the brain and the spinal cord of infected mice.

It is apparent that the lesions described above provide an almost complete explanation of the signs and symptoms of yellow fever. Damage of the liver causes hemorrhage and changes in metabolism; albuminuria is due to degenerative changes in the kidney, bradycardia and low blood pressure to involvement of the heart; lymphopenia results from involvement of the lymphoid tissue of the spleen and lymph glands Unfortunately, no studies have been made on the bone marrow of man or monkey dead of yellow fever The marked leukopenia suggests that the myelogenic centers may be affected

Support for most of the above statements has been obtained by a study of the mode of spread and the sites of multiplication of yellow fever virus in rhesus monkeys It has been shown that, following an intradermal inoculation, virus spreads immediately to the local lymph glands where multiplication occurs. After several days, it enters the blood stream and infects the liver, the spleen, the kidneys, bone marrow, and lymph nodes If a monkey survives, virus can still be demonstrated in the lymph nodes, the spleen and bone marrow for several days after the blood has become virus-free There is a clear distinction of the organs involved, depending on the virulence of the virus With highly virulent strains, such as the Asibi, the highest titer of virus is found in the liver On the other hand, the almost avirulent 17D strain can be demonstrated only in spleen, lymph nodes and bone marrow Strains of virus intermediate between these two, for example the mouse-adapted French neurotropic strain, follow more closely the pattern of the Asibi, however, the titers of virus obtained in the liver and blood are not so high (Theiler, 1951)

Yellow fever in monkeys, and presumably in man, is basically an infection of the hemapoietic system and only secondarily involves other organs Almost all lesions can be explained on the basis of infection by and multiplication of the virus Death occurs probably as a direct result of damage done by the virus in the liver and the kidney.

EXPERIMENTAL INFECTION; HOST RANGE

Yellow fever virus shows marked tissue affinities. Unmodified virus is pantropic, showing affinity for all 3 embryonal layers By viscerotropism is meant affinity of the virus for the abdominal viscera, particularly the liver The rhesus monkey is the experimental animal largely used for demonstrating this property All yellow fever viruses exhibit some neurotropism, the common albino mouse is the animal of choice for demonstrating this By various experimental means, both of these attributes can be modified

Strains of yellow fever virus differ in pathogenicity Thus, most strains of African origin are highly pathogenic for rhesus monkeys, almost invariably producing a fatal infection, with death due to an acute necrosis of liver cells In such infections the virus invades the blood stream, where it is present in high concentration. On the other hand, most South American strains when inoculated by extraneural routes have little capacity to destroy visceral cells, rarely producing death from liver necrosis; the only manifestation of infection may be the presence of virus in the blood When a highly viscerotropic strain is inoculated into the brain of a rhesus monkey, death occurs as a result of liver damage and not encephalitis However, the essential neurotropism of such a strain can be shown if, at the time virus is inoculated intracerebrally, the liver is protected by an injection of specific, immune serum A monkey so inoculated will develop fatal encephalitis.

The modification of yellow fever virus is accomplished most readily by serial intracerebral passages in mice (Theiler, 1930) This procedure leads to two predictable results (1) the incubation period and the course of the disease in the mice become shorter, and (2) the pathogenicity for monkeys by parenteral inoculation is diminished. *Pari passu* with this loss of viscerotropism there is an enhancement of neurotropism All yellow fever viruses so far studied, if serially passaged in

munity produced by previous infection with another virus belonging to Group B. However, among Africans, severe epidemics with a number of deaths, such as that which occurred in the Nuba Mountains in Africa, have been reported (Kirk, 1941). Opinions differ as to whether the disease in children is as severe as in adults It is very difficult to evaluate the over-all mortality of yellow fever This is usually high in cases in which black vomit and jaundice occur. However, experience has shown that for every case diagnosed, there are usually a great many undiagnosed mild infections as shown by the development of specific neutralizing antibodies Taking into account missed cases, the mortality is probably seldom greater than 5 per cent

PATHOLOGIC PICTURE

The outstanding macroscopic findings in yellow fever are signs of degeneration in the liver, the kidney and the heart, accompanied by hemorrhages and jaundice The cadaver usually has a livid appearance, due to venous congestion Since the blood in fatal yellow fever remains fluid for a long time, it collects in the dependent portions of the body. Jaundice is always present, seldom well marked. The liver is of normal size or slightly enlarged, somewhat yellow in color, and fatty on section; when drained of blood, it has a boxwood color The tense and swollen kidneys are likewise fatty and yellow, the cortex is not clearly demarcated from the medulla. Evidence of hemorrhage is usually found, the most frequent site is in the mucosa at the pyloric end of the stomach, where erosions and punctate hemorrhages are present. In very few cases is there a complete absence of altered blood in the stomach contents

On microscopic examination, the most characteristic lesions are found in the liver (da Rocha Lima, 1912). The liver cells undergo cloudy and fatty degeneration and a distinctive type of necrosis The necrotic cells are mainly confined to the midzone, although in severe cases the necrosis may involve almost the entire lobule In such cases, however, there will always be found a few normal-appearing cells about the central vein and about the periphery of the lobule. Furthermore, all cells in the midzonal section may not be destroyed, resulting in a spotty distribution of the necrotic areas. The necrosis is hyaline in type and may be confined to part of the cytoplasm, but usually the whole cell is involved. Such necrotic, hyaline cells are known as Councilman bodies. The Kupffer cells are enlarged and may be granular in appearance. The sinusoids in the necrotic areas are engorged Actual hemorrhage in the liver is rare. In spite of extensive necrosis, the architecture remains intact During recovery the parenchymatous cells are replaced, leading to a complete restoration of the liver without residual signs of infection such as cirrhosis.

The lesions observed in the kidney are not distinctive. As in the liver, there is a complete absence of inflammatory reaction Cloudy and fatty degeneration of the entire kidney tubule, often more marked in the convoluted portion, is usually present. EXPERIMENTAL INFECTION; HOST RANGE

Yellow fever virus shows marked tissue affinities Unmodified virus is pantropic, showing affinity for all 3 embryonal layers By viscerotropism is meant affinity of the virus for the abdominal viscera, particularly the liver. The rhesus monkey is the experimental animal largely used for demonstrating this property All yellow fever viruses exhibit some neurotropism; the common albino mouse is the animal of choice for demonstrating this. By various experimental means, both of these attributes can be modified

Strains of yellow fever virus differ in pathogenicity Thus, most strains of African origin are highly pathogenic for rhesus monkeys, almost invariably producing a fatal infection, with death due to an acute necrosis of liver cells In such infections the virus invades the blood stream, where it is present in high concentration On the other hand, most South American strains when inoculated by extraneural routes have little capacity to destroy visceral cells, rarely producing death from liver necrosis; the only manifestation of infection may be the presence of virus in the blood When a highly viscerotropic strain is inoculated into the brain of a rhesus monkey, death occurs as a result of liver damage and not encephalitis However, the essential neurotropism of such a strain can be shown if, at the time virus is inoculated intracerebrally, the liver is protected by an injection of specific, immune serum. A monkey so inoculated will develop fatal encephalitis

The modification of yellow fever virus is accomplished most readily by serial intracerebral passages in mice (Theiler, 1930) This procedure leads to two predictable results. (1) the incubation period and the course of the disease in the mice become shorter, and (2) the pathogenicity for monkeys by parenteral inoculation is diminished *Pari passu* with this loss of viscerotropism there is an enhancement of neurotropism All yellow fever viruses so far studied, if serially passaged in

mouse brains, acquire the ability of producing a fatal encephalitis in rhesus monkeys, most readily shown by intracerebral inoculation However, from 5 to 10 per cent of rhesus monkeys inoculated subcutaneously may die of encephalitis The survivors acquire a solid immunity to a subsequent infection with highly viscerotropic virus That the mouse-adapted virus has not entirely lost its viscerotropic affinity can be shown readily by the demonstration of circulating virus In fatal encephalitis, produced either by intracerebral or by parenteral inoculation, the virus is widespread in the peripheral nervous system At the time of death it can be recovered from the brain, the spinal cord, the retina, peripheral nerves, salivary glands and adrenal glands but not from the blood, the cerebiospinal fluid or the liver. Neutralizing antibodies are present at the time of death

A further loss of virulence has been produced by prolonged cultivation in tissue culture (Lloyd et al, 1936) One of the variants, known as the 17D strain, is used extensively for human vaccination (Theiler and Smith, 1937a) and has lost to a considerable extent both its viscerotropic and neurotropic affinities (Theiler and Smith, 1937b) On subcutaneous inoculation of it into rhesus monkeys, a mild systemic infection occurs which can be demonstrated by the presence of minimal amounts of virus in the circulation; on intracerebral inoculation, it produces an encephalitis which is fatal in only about 5 per cent of animals

In addition to the rhesus monkey, it has been found that all South American and African species of monkey so far tested are susceptible to the virus of yellow fever. In most instances, the infection is comparatively mild and accompanied only by a temporary invasion of the blood stream and the development of specific antibodies However, the invasion of the blood is sufficient for mosquitoes to be infected readily by feeding on the monkeys, as a rule, thus indicating the possibility of these animals acting as hosts for the maintenance of virus cycles in nature.

Adult mice are very susceptible to the virus after intracerebral, less after intranasal, and seldom after intraperitoneal inoculation. However, immature mice are highly susceptible to the virus administered by all routes of inoculation. In both adult and infant mice, at the time of death, the virus can be demonstrated only in nervous tissue and in the adrenal gland, an organ which is developmentally a part of the nervous system With age, mice rapidly acquire a resistance to virus inoculated peripherally (Bugher, 1941). This resistance is quite apparent at 9 days of age. Mice younger than this are just as susceptible to neurotropic and viscerotropic strains of virus inoculated subcutaneously as adult mice are to similar strains given intracerebrally. The susceptibility of infant mice to peripheral inoculation has been used to determine the infectivity of mosquitoes in transmission experiments Not all strains of mice are equally susceptible to yellow fever (Sawyer and Lloyd, 1931), of the strains available to these authors, the Swiss strain proved to be the most suitable.

The rabbit and the rat are completely resistant to the virus The guinea pig is, as a rule, susceptible to virus when injected intracerebrally, developing a fatal encephalitis Different strains of guinea pig vary in their response to extraneural inoculation Some are highly susceptible, developing a symptomless, systemic infection, as demonstrated by the presence of virus in the circulation; others appear to be completely resistant (Theiler, 1951)

In the search for possible hosts of jungle yellow fever, the susceptibility of numerous wild animals has been studied (Bugher, 1951) To date, birds, cold-blooded animals, mammals belonging to the orders of *Carnivora* and *Chiroptera*, and most rodents have been shown to be resistant to virus inoculated extraneurally. In most of these groups, very few species have been studied and, as a rule, only adults Animals which have been found to be susceptible include the peccary, several species of edentates (anteaters, armadillos and sloths), a few rodents and all American marsupials Most of these animals are only moderately susceptible, as minimal amounts of circulating virus are present.

The classic urban type of yellow fever is transmitted by *Aëdes aegypti*. The experiments of Reed et al (1911) showed that this mosquito becomes infected by biting a patient during the first 3 days of the disease and that an interval of approximately 12 days

must elapse before it can transmit infection by bite Subsequent work has shown that, under experimental conditions, this extrinsic incubation period can be as short as 4 days and as long as 3 weeks if the mosquitoes are kept at 37° C. or 20° C, respectively (Davis, 1932). A mosquito once infected remains infective for life and harbors the infection without any ill effect There is no evidence that the virus can pass to the next generation through the egg

Evidence is conclusive that yellow fever virus actually multiplies in the mosquito (Whitman, 1937) Following an infective blood-meal the virus in the mosquito diminishes, reaching a minimum during the first week It then increases rapidly until quantities far greater than the amount ingested can be demonstrated Very little is known concerning the relative efficiency of various mosquitoes, shown to be capable of transmitting the virus, to act as intermediate hosts Moreover, it is not known whether the *Aëdes aegypti* mosquito is equally efficient as a vector in its many homes throughout the world Finally, it is not known whether or not all strains of yellow fever virus are equally capable of infecting susceptible mosquitoes From the human experiments of Reed et al (1911), one is warranted in concluding that under the conditions of their work, the *aegypti* mosquitoes used by them became infected readily, as they had no difficulty in transmitting the disease by the bite of from 1 to 15 mosquitoes

The optimum conditions under which mosquitoes become infected is not known. Bates and Roca-García (1945) had difficulty at first in experimentally infecting *Haemagogus* mosquitoes, although numerous infected mosquitoes of this species, capable of producing infection in experimental animals by bites, had been caught in nature Finally, it was discovered that laboratory-fed mosquitoes, if kept at 30° C, are able to transmit the infection readily by bite In these experiments, not only was the extrinsic incubation period shortened by the higher temperature but the percentage of mosquitoes becoming infected was increased Whitman and Antunes (1938) showed that mosquito larvae can be infected by immersion in virus preparations, male and female adults, which are derived from these larvae, are infected, and the females are capable of transmitting the disease by biting

Of African mosquitoes, in addition to *Aëdes aegypti*, the following have been shown experimentally capable of transmitting the virus by bite· *Aëdes luteocephalus*, *A. stokesi*, *A vittatus*, *A africanus*, *A. simpsoni*, *A. taylori*, *A metallicus*, *Eretmopodites chrysogaster*, *Taeniorhynchus africanus* and *Culex thalassius* South American mosquitoes capable of acting as experimental hosts are *Aedes scapularis*, *A. fluviatilis*, *A leucocelaenus*, *Trichoprosopon frontosus*, *Sabethes chloropterus* and various members of the genus *Haemagogus* Species identified as *Haemagogus capricornii*, *H spegazzinii*, *H splendens*, *H uriartei*, *H mesodentatus* and *H equinus* have been shown to be capable of transmitting the virus However, very few of these mosquitoes have actually been incriminated in the epidemiology of yellow fever In South America, yellow fever virus has been isolated on numerous occasions from wild-caught species of *Haemagogus* and several times from *Aedes leucocelaenus* In Africa, *Aëdes simpsoni*, *A. africanus* and *A aegypti* have been found infected in nature (Whitman, 1951)

Mosquitoes are the only bloodsucking arthropods which have been definitely shown to play a part in the epidemiology of yellow fever Miscellaneous experiments have been made with a great variety of other arthropods, such as ticks, mites, fleas, lice, triatomas and bloodsucking flies However, none of these was found capable of transmitting the disease (Whitman, 1951)

ETIOLOGY

Early investigations of the properties of yellow fever virus were made by means of human volunteers, who were used by the American Army Commission under Walter Reed in Havana in 1901 (Reed et al, 1911) Therefore, work was extremely limited, but it was possible to show that the virus passed through filters which retained bacteria When experimental animals became available, it was shown that the etiologic agent of yellow fever is one of the small viruses It readily passes through Seitz as well as all grades of Berkefeld and Chamberland filters By the use of collodion membranes of graded porosity

(gradocol membranes), its diameter has been estimated to be from 17 to 25 mμ The particle size of neurotropic and viscerotropic strains appear to be identical.

The virus of yellow fever is extremely labile; it is readily inactivated by heat and the usual antiseptics It can be preserved in 50 per cent glycerol for several months. The best method for the preservation of the virus is through desiccation while in the frozen state, and storage in a refrigerator, under such conditions it may remain viable for many years. Storage of frozen material in a dry-ice container is convenient and satisfactory, provided that the ampules are sealed Dilution in physiologic salt solution quickly inactivates the virus (Bauer and Mahaffy, 1930). The deleterious action of salt can be prevented by incorporating 10 per cent normal serum or 0 75 per cent bovine plasma albumin in the diluent

Neurotropic yellow fever virus can be cultivated readily in a Maitland-type of tissue culture. However, it was found difficult to adapt an unmodified pantropic strain to tissue culture, the first success was obtained by Lloyd et al (1936), who were able to grow the Asibi strain in a medium containing minced mouse-embryo tissue After some passages, successful cultivation was obtained in a medium containing minced chick embryo In studies to determine whether or not the amount of nervous tissue in the medium had an influence on the neurotropic affinity of the virus, several parallel series of cultures were established containing varying amounts of nervous tissue In the series, containing minimal amounts of nervous tissue, a marked modification of both the viscerotropic and the neurotropic affinities occurred. From these experiments came the 17D strain, now extensively used for vaccination

Yellow fever virus can be maintained in the developing chick embryo. Pantropic, unmodified strains are established with difficulty, but strains which have been maintained in tissue culture or by serial passage in mouse brains are established readily. The chick embryo is used as a routine for the production of vaccine from the 17D strain. Penna and Moussatche (1939) studied the effect of serial passage in the chick embryo on a pantropic strain After a few passages in tissue culture, they established the Asibi strain in chick embryos and noted not only that the viscerotropism of the cultivated strain decreased but that the neurotropism for monkeys was markedly diminished. They were thus able to produce a strain like the 17D. It is noteworthy that in Penna and Moussatche's experiments the marked attentuation occurred in an environment containing large amounts of nervous tissue, for it is known that in the developing chick embryo the brain is one of the main sites of virus multiplication.

Yellow fever virus infection gives rise to neutralizing, complement-fixing and hemagglutination-inhibiting antibodies The presence of neutralizing or protective antibodies is determined by neutralization tests in mice. Various tests are available. In the most sensitive, infant mice and the intraperitoneal route of inoculation are used Adult mice are not susceptible to this route of inoculation However, if at the time of inoculation the brain is damaged by the injection of a sterile solution of starch, infection will take place This is the basis of the intraperitoneal protection test of Sawyer and Lloyd (1931) which was used on a vast scale to map the distribution of yellow fever immunity throughout the world (Smith, 1951) The main drawbacks of the intraperitoneal protection test are the difficulty of standardization and the relatively large quantities of serum required

The intracerebral protection test (Theiler, 1933; Bugher, 1940) consists of mixing the sera to be tested with a suspension of standardized virus stored in sealed ampules at the temperature of dry ice. Several preliminary titrations of the virus preparation make it possible to dilute it so that when mixed with the serum and inoculated in 0 03 cc amounts each mouse receives 100 LD_{50} To determine the end point in virus titrations, the method used is that of Reed and Muench (1938), giving the theoretical dilution that will kill half the number of inoculated mice

The complement-fixation reaction has been studied extensively in yellow fever (Davis, 1931; Lennette and Perlowagora, 1943) Antigens capable of fixing complement are found in the liver and the serum of infected monkeys and in the brains of infected mice The antigen can be demonstrated only in the serum of severely ill monkeys; this probably applies also to human infections

The complement-fixing and protective antibodies are not identical. In man and in experimentally infected monkeys, protective antibodies are sometimes demonstrable before complement-fixing antibodies. Furthermore, in very mild infections, such as that produced by vaccination, complement-fixing antibodies may be absent (Lennette and Perlowagora, 1943). Complement-fixing antibodies disappear comparatively rapidly, consequently, survey for their presence in a population affords information only of yellow fever in the immediate past On the other hand, protective antibodies persist for a long time, if not throughout life, and a survey for them gives an accurate index of the total exposure of a population to yellow fever

DIAGNOSIS

During an epidemic, a diagnosis of yellow fever can often be made on clinical grounds, if the patient shows classic signs and symptoms However, very mild or atypical cases occur in which a diagnosis on clinical grounds usually is impossible Three laboratory procedures are available to establish a diagnosis. (1) isolation of the virus, (2) demonstration of the development of specific antibodies during the course of the disease, and (3) pathologic examination of the liver in fatal cases

For the isolation of virus, serum obtained from a patient, as early in the disease as possible, is inoculated intracerebrally into mice Due to the greater susceptibility of infant mice, these should be employed whenever possible Virus can generally be isolated during the first 4 days of disease On several occasions, successful isolations have been obtained on the fifth and the sixth and on one occasion even on the twelfth day after onset (Downs et al, 1955) In fatal cases virus can at times be isolated from the liver (Anderson and Wattley, 1955) Mice, after a variable incubation period which depends on the concentration of virus in the blood as well as its virulence, develop signs of encephalitis Inasmuch as the signs of disease in the mouse are not specific for yellow fever, the agent thus isolated from a patient must be identified by various means The commonest method is by means of the neutralization test In this, the action of a yellow fever immune serum of known potency is determined on the newly isolated virus If this serum neutralizes the virus under study to approximately the same amount as it neutralizes a known yellow fever strain, it is good evidence that the isolate is a strain of yellow fever.

An alternative method of identification is to prepare a complement-fixing antigen from the brains of infected infant mice and to identify the agent by means of complement-fixation tests If in a box or grid titration a yellow fever immune serum fixes complement to the same extent in the presence of an antigen made from the newly isolated virus as it does in the presence of an equivalent number of units of a known yellow fever antigen, this is very good evidence that the virus is a strain of yellow fever.

In attempts to isolate yellow fever virus from man, it must be borne in mind that some strains of the agent act in a paradoxical manner. Thus, none of a group of mice inoculated with undiluted serum may become infected, whereas the same serum diluted 10- or 100-fold will cause encephalitis in the inoculated animals Therefore, serum to be tested should be inoculated undiluted and in several dilutions into groups of mice By passage in mouse brains, this peculiarity is lost rapidly

Monkeys can also be used for the isolation of yellow fever virus However, it must be realized that the strain of yellow fever may not be lethal for the species of monkey used, consequently, an inoculated animal subsequently is tested for circulating virus at regular intervals by the injection of its serum into mice The virus isolated in the mice is then identified in the manner described above Finally, in the case of survival, the serum of the monkey is tested for specific antibodies Rhesus monkeys have been used most extensively for the isolation of yellow fever virus However, all species of monkey so far studied have been found to be susceptible

As facilities for animal inoculation are not always available, often a diagnosis can be established by the examination of two specimens of serum by serologic means The serologic reaction following yellow fever infection can be of two types, depending upon whether the infection is primary or whether it occurs in an individual who had previously been infected with another agent belonging to Group

B of arbor viruses (Theiler and Casals, 1958) In a primary infection, the antibodies produced are remarkably specific, enabling a diagnosis to be made with assurance, whereas, in the case of a superinfection, antibodies with wide overlaps with other members of the group are produced, making a specific diagnosis virtually impossible. The demonstration of a rise in yellow fever antibodies is of itself not conclusive evidence that the infection was due to yellow fever unless it can be shown that the infection was a primary one For this purpose, the most conclusive evidence is given by complement-fixation tests performed with the convalescent serum In a primary yellow fever infection, the complement-fixing antibodies are often remarkably specific, the convalescent serum fixing complement only with a yellow fever antigen At times there is some fixation with other Group B antigens, but this is always at a much lower titer In the event of a superinfection, the complement-fixation test is completely nonspecific, the convalescent serum fixing complement to a high titer with a wide variety of Group B antigens Hemagglutination-inhibition tests with paired sera supply information of a similar nature In a primary infection HI antibodies of reasonable specificity appear early in the course of the disease The titers of HI antibodies to yellow fever are invariably as high as or higher than antibodies to other Group B agents In superinfections, the pattern of HI antibodies, like the CF antibodies, are not distinctive A further distinction between primary and superinfections is that in the latter antibodies appear very rapidly and develop to a high titer

The diagnosis of fatal yellow fever by the examination of the liver plays a very important part in those countries where the disease is endemic In certain countries, notably Brazil and Colombia, where yellow fever occurs over an enormous area, the systematic study of liver sections of persons who have died of an acute febrile disease of less than 10 days' duration, is a very important function of the Yellow Fever Service (Rickard, 1937). The viscerotome, a simple instrument by which small portions of liver can be obtained from a cadaver, is used This instrument can be employed by a lay person. The portions of liver thus obtained are fixed in formalin solution, embedded in paraffin, and stained with hematoxylin and eosin Diagnosis is based on the presence of typical lesions.

TREATMENT

There is no specific treatment. Complete rest in bed and careful nursing are essential for even the mildest cases Solid food should be withheld Fluids should be forced If persistent vomiting occurs, saline solution may be given by epidermoclysis, and glucose by intravenous injection Cracked ice by mouth may relieve vomiting If this fails, codeine sulfate by hypodermic injection or cocaine hydrochloride by mouth should be given High temperature may be relieved by tepid water sponges To relieve the headache, ice caps may be used, however, it may be necessary to give an analgesic such as codeine sulfate In view of the tendency to constipation, a laxative should be given early in the disease, and thereafter daily enemas should be administered.

EPIDEMIOLOGY

Following the development of the protection test and its application to the study of the world-wide distribution of immunity to yellow fever, several important facts were established. It was shown that yellow fever as it occurred years ago in Cuba, New Orleans, and Panama was immunologically the same as that which is encountered at the present time. The identity of the disease in Africa and America has been clearly established The presence of immunity to yellow fever was shown to be confined to the American and the African continents However, an analysis of the age distribution of protective antibodies indicated that yellow fever is now no longer present in places where it had formerly been prevalent Thus, no evidence was found of any immunity to yellow fever in persons born in Cuba or New Orleans since the last reported epidemics in these places during the first few years of this century.

In Africa and South America the zone of immunity to yellow fever was found to be unexpectedly large. The limits of the area in which antibodies to yellow fever were found in children, and hence areas where the infec-

tion has been present in recent years, comprise the bulk of the tropical zones in the two continents In South America this endemic zone consists of the major portion of the Amazon and the Orinoco basins, in addition to the greater part of Colombia, the Republic of Panama, and the Guianas (Soper, 1938). In this enormous region, *Aedes aegypti* is not universally present so that, clearly, in many places the infection was transmitted in the absence of this vector In Africa, previous to the modern era of research, yellow fever had been reported only along the west coast in a comparatively narrow zone, extending from Dakar to the mouth of the Congo Actually, persons with antibodies capable of neutralizing yellow fever have been found in an area extending from the Atlantic to the Indian Ocean The northern boundary is the Sahara from Dakar to the Eritrean coast on the Red Sea The southern boundary has not yet been clearly demarcated but extends into Northern Rhodesia

Two main epidemiologic entities are distinguished, based on the habits of the vector, the classic urban aegypti-transmitted infection and jungle or sylvan yellow fever, a disease essentially of wild animals and transmitted to man only secondarily

Aedes aegypti is confined to the tropics, with extensions both north and south into the temperate zones This mosquito, like other species belonging to the subgenus *Stegomyia*, is an old-world species and probably was introduced into the western hemisphere during the time of the slave trade The female *Aedes aegypti* prefers to oviposit in water in artificial containers Thus it is essentially a domestic mosquito breeding in houses or in their immediate vicinity This domesticity seems to be more marked in America than in Africa, where it has been captured in small numbers even in primeval forest It is probable that *Aedes aegypti*, like the other species of the subgenus *Stegomyia*, was originally a tree-hole breeder Although this species is present in the tropical zones of the entire world, aegypti-transmitted yellow fever has been reported only in the Americas, Africa and Europe Northward or southward extension of the disease outside the tropics has occurred only during the warm season of the year when climatic conditions were favorable for the mosquito, with the advent of winter epidemics ceased

Being transmitted by *Aëdes aegypti*, a domestic mosquito, urban yellow fever is a household disease affecting all ages and both sexes equally The virus cycle, man-mosquito-man, necessitates an abundance of both the vertebrate and the invertebrate hosts for its maintenance in a community. It follows, therefore, that it is only in relatively large centers of population with a constant influx of susceptibles that this form of yellow fever can persist for any length of time In an aegypti-transmitted epidemic the natural course of events leads to a gradual diminution of the number of susceptibles due to immunization or death Consequently, as the epidemic progresses, more mosquitoes are necessary to maintain the virus cycle Although centers of population with an adequate number of susceptible people are usually large towns, this is not necessarily so An area containing numerous small collections of people with frequent communication between them may remain infected for a long time The infection in such areas wanders from place to place This condition is present in large parts of tropical Africa, and at one time prevailed in Yucatan and in the northeastern portion of Brazil In the last region, owing to the extreme scarcity of water during the dry season, every house had its own water storage. So scarce was water at times that people visiting neighboring villages and farm houses would carry their own drinking water with them In this manner *Aedes aegypti* was widely spread throughout the rural area, and when yellow fever was eradicated from the towns and the villages, it still managed to maintain itself in the comparatively sparsely populated rural area Here, therefore, was the phenomenon of rural yellow fever transmitted by *Aedes aegypti*

The disappearance of yellow fever following the initiation of antimosquito measures was so striking that public health authorities became convinced that the man-*aegypti*-man cycle was the only one. As the war against *Aedes aegypti* progressed, yellow fever apparently disappeared from large areas, and the authorities were justified in their opinions.

However, in spite of success attending the anti-aegypti campaigns, observations were

made that did not fit into the accepted theory. Thus, yellow fever was reported repeatedly from the emerald mines of Muzo in Colombia. Competent investigators came to the conclusion that the disease in Muzo could not be yellow fever, and this conclusion was based largely on the absence of *Aëdes aegypti* in that region Renewed interest in Muzo occurred following aegypti-transmitted epidemics of yellow fever in the nearby towns of Bucaramanga and Socorro. These towns are very isolated, and it was a mystery how the infection was introduced By the use of the protection test, it was shown that immunity to yellow fever was very prevalent in rural, aegypti-free districts, including the Muzo region (Kerr and Patiño Camargo, 1933) Conclusive evidence that yellow fever can occur in rural areas in the absence of *Aedes aegypti* was furnished by the isolation of yellow fever virus during an epidemic which occurred in the Valle do Chanaan, Brazil, in 1932 (Soper et al, 1933) Extensive surveys of immunity to yellow fever clearly demonstrated that the disease was widely distributed in South America in many places where *Aedes aegypti* does not exist

The epidemiologic entity, jungle yellow fever, occurs in South America either in epidemic or endemic form In the endemic form the disease is almost constantly present, and human cases occur year after year The factors concerned in determining human infection in an endemic region have been studied by Soper (1938), Taylor and da Cunha (1946), and Laemmert et al. (1946) Cases of jungle yellow fever are confined almost entirely to adult males This is due to the fact that, as a rule, only the adult male enters the forest to work, clear the jungle, hunt, etc. The infection acquired in the jungle usually is not transmitted to the women and the children, as the common domestic mosquito *Aëdes aegypti* is absent The intimate relationship between the incidence of jungle yellow fever and contact with forest is an adequate explanation of the peculiar sex and age distribution of immunity in a population exposed to the disease, which is quite different from that seen in aegypti-transmitted infections.

Numerous observations in various parts of South and Central America have shown that species of mosquito belonging to the genus *Haemagogus* play an important role in the epidemiology of jungle yellow fever. On many occasions yellow fever virus has been isolated from *Haemagogus* mosquitoes Man is infected only secondarily in a virus cycle in the jungle As yet, the virus cycle or cycles have not been entirely established It is known, however, that various species of monkey play an important role Thus, in most regions where cases of jungle yellow fever have occurred, a considerable proportion of the monkeys show neutralizing antibodies to yellow fever virus Furthermore, in the study of endemic jungle yellow fever in the Ilheus region, yellow fever virus was isolated on 4 separate occasions from marmosets (Laemmert et al, 1946) Extensive investigations in this region failed to produce evidence that any other vertebrate was involved, and *Haemagogus spegazzinii* appeared to be the only vector.

Although it is reasonably certain that primates and *Haemagogus* mosquitoes play an important role in the maintenance of jungle yellow fever virus in nature, there still are many unexplained observations Thus, in the Muzo region, which is a true endemic area, monkeys are either rare or absent. Bugher et al. (1944) have presented evidence that in such areas species of marsupials may act as vertebrate hosts. With certain species of marsupials, yellow fever virus infection can be maintained experimentally by means of mosquitoes. The commonest species, the opossum (*Didelphis marsupialis*), is not very susceptible to the virus. However, Bugher et al (1944) have presented evidence that in jungle yellow fever areas this species shows a high incidence of neutralizing antibodies.

In addition to endemic jungle yellow fever, there is the epidemic type The epidemic form has a tendency to spread farther each year. The most extensive epidemic studied was that of 1933-1938 (Soper, 1938). Presumably originating in the Amazon basin, it spread southeastward through Brazil The spread lasted several years During the colder portions of the year, the infection apparently disappeared, to recommence with the advent of the next summer. The first cases in the new season were often a considerable distance ahead of the last cases of the previous season This wave spread diagonall throughout

Brazil, reaching the Atlantic coast at Rio de Janeiro and then spreading northward along the coast to die out spontaneously It was during this epidemic wave that the genus *Haemagogus* was first shown to play some part in the epidemiology of the disease

An epidemic spread of jungle yellow fever in Central America causing great concern to public health officials is still in progress at the time of writing (Soper, 1955) Previous protection test surveys had indicated that yellow fever, though at one time abundant in Central America, had disappeared from this region. The last epidemic north of the Panama Canal occurred in 1924 in Salvador. The disappearance of yellow fever from this region had been ascribed to the efficacy of *Aedes aegypti* suppression in the key centers The present epidemic wave originated in Eastern Panama in 1948 The disease has moved steadily northward through the rain forest, passing successively through Costa Rica, Nicaragua, Honduras, and Guatemala. The wave of this epidemic was readily followed by a high mortality among the monkeys, particularly the howler monkey This epidemic spread northward, occurring only during the rainy season when *Haemagogus* mosquitoes were abundant Yellow fever virus was isolated from wild-caught *Haemagogus mesodentatus*, *H equinus* and *Sabethes chloropterus* (de Rodaniche and Galindo, 1957) The last mosquito is of special interest because it has a long life and is relatively abundant during the dry season. Thus, it may be able to maintain the virus cycle during the interepidemic seasons (Galindo et al., 1956)

Of unusual interest is the epidemic of yellow fever which occurred in Trinidad in 1954 (Downs, 1955) Apparently, the island had been free of the disease since 1914 The recent epidemic was primarily of the jungle variety, accompanied by a high mortality of howler monkeys. The main vector was *Haemagogus spegazzinii* On 22 occasions, strains of yellow fever were isolated from pools of this species The diagnosis of yellow fever was confirmed in 12 nonfatal cases by the isolation of virus from the blood and in 4 fatal cases by virus isolation from the liver or by histopathologic examination Additional human cases were diagnosed subsequently by serologic methods It was apparent that the epidemic was much more extensive than anyone realized at the time. It is estimated that there were hundreds of cases of unrecognized yellow fever in Trinidad during 1954. *Aedes aegypti* was widely distributed on the island, being present not only in the larger towns but also in the smaller villages situated in the forest. Epidemiologic investigations indicated that several of the rural cases in all probability acquired their infections by the bite of this mosquito However, it is noteworthy that in spite of the prevalence of *Aëdes aegypti* in the towns no epidemic of the classic aegypti-borne type occurred The epidemic on the island developed with great rapidity, and the infection was widely distributed before control measures could be instituted These consisted of mass vaccination and an island-wide anti-aegypti campaign

Somewhat similar conditions are found in Africa. As *Aëdes aegypti* is distributed more widely in Africa than in South America, at times it is difficult to make a clear distinction between the two epidemiologic types of the disease However, conclusive evidence has been obtained that primates act as vertebrate hosts of the virus The most likely invertebrate host in the forest is *Aedes africanus*, which is most active at twilight and at night and prefers the upper foliage As in the Americas, man plays no part in the maintenance of the virus cycle in the jungle Because the habitat of *Aedes africanus* is in the forest canopy, it is extremely unlikely that this mosquito infects man in the forest

The sequence of events seems to be as follows Certain species of monkey have the habit of raiding human plantations On the edge of the forest and on the plantation, another mosquito, *Aedes simpsoni*, occurs, which is a plant-axil breeder Presumably, this mosquito becomes infected from monkeys and then transmits the disease to man. Under experimental conditions both *Aedes africanus* and *Aedes simpsoni* are efficient vectors of the disease Yellow fever virus has been isolated from *A simpsoni* caught in a region where cases of yellow fever were occurring (Smithburn and Haddow, 1949) and from *Aedes africanus* caught in the uninhabited forest

in sufficient numbers to be considered as a possible vector.

The classic urban, aegypti-borne yellow fever is comparatively common in Africa. This is the type which has been frequently observed in West Africa. Extensive epidemics of rural yellow fever also occur. This type may or may not be transmitted by *Aedes aegypti*. The most extensive epidemic of this type, and one of the most severe described in recent years, is that which occurred in the Nuba Mountains in the Anglo-Egyptian Sudan in 1940 (Kirk, 1941). Over 15,000 cases were recorded, with more than 1,500 deaths. A survey for immunity to yellow fever after the epidemic indicated that approximately 40,000 cases must have occurred. *Aedes aegypti*, although present, was, on epidemiologic grounds, not the principal vector. *Aëdes vittatus*, *Aëdes taylori*, and *Aedes metallicus*, all known to be efficient vectors under experimental conditions, were present in the region, and one of them was probably the main vector in the epidemic.

Recent investigations, using the infant mouse neutralization test, have shown conclusively that sera from individuals who have previously experienced infections with a variety of Group B agents such as dengue, West Nile, Ilheus and Japanese B have the capacity of neutralizing yellow fever virus. These observations strongly suggest that individuals who have experienced a Group B virus infection are relatively immune to yellow fever and may account for many of the mild clinical cases. These observations also suggest the possibility that, in a population largely immune to dengue or other Group B viruses, it may be difficult or even impossible for an epidemic of aegypti-transmitted yellow fever to occur. During the recent epidemic of jungle yellow fever in Trinidad (Downs, 1955), it was noteworthy that in spite of the fact that *Aëdes aegypti* was abundant in Port-of-Spain, the capital, no aegypti-borne epidemic occurred. The incidence of antibodies to dengue is very high in Port-of-Spain. The marked immunologic overlaps among the Group B viruses may afford an explanation for the absence of aegypti-borne yellow fever in regions of the world where this mosquito is abundant and, consequently, where conditions appear to be favorable for the maintenance of yellow fever infections.

CONTROL MEASURES

Prior to the development of methods of vaccination anti-aegypti measures were the only ones available for the control of yellow fever. Their efficacy was clearly established by Gorgas and others immediately following the demonstration that *Aedes aegypti* acted as a vector. Following the successes in Havana, New Orleans, Panama, Río de Janeiro and Guayaquil, these methods became firmly established. The measures employed were at first confined to the control of breeding. This was achieved by a weekly search for larvae in and in the immediate vicinity of every house. Inspectors had authority to pour oil into any container found to harbor *Aedes aegypti* larvae. This procedure has a 2-fold effect: (1) the oil kills the larvae, and (2) the householder is impelled to clean the container. The difficulty of cleaning receptacles after oil has been poured into them induces the householder to do everything possible to prevent mosquito-breeding. Such weekly inspection and eradication of all breeding places are adequate to reduce the number of adult mosquitoes below a level where transmission is possible. However, this procedure is not sufficient to eradicate the mosquito entirely, because hidden breeding foci are not discovered during routine inspections. In order to find these, specially trained inspectors are employed. Their function is to make captures of adult mosquitoes in every

in that house in which the largest number of adult mosquitoes is found. By these means it is possible to find every breeding focus in a town and, consequently, to eradicate *Aëdes aegypti*. From an administrative point of view, it has been found cheaper to eradicate *Aedes aegypti* than to keep the mosquito population below a critical level. The latter necessitates a permanent inspection force to prevent the re-establishment of a large mosquito population. Following eradication, reinfestation does not occur readily, and a skeleton force is suf-

ficient to verify the continued absence of the mosquito, particularly if similar anti-aegypti measures are employed in nearby towns In Brazil, anti-aegypti measures have been employed so extensively that for several years no cases of yellow fever have been reported as being aegypti-borne. In fact, the species has been eradicated from entire states A very active campaign is being waged at present in an effort to eradicate *Aedes aegypti* from the Americas

In Africa the situation in regard to the control of *Aëdes aegypti* is not so favorable In the first place, *Aëdes aegypti* is distributed far more widely Secondly, this species does not seem to be as domestic as in the Americas In fact, specimens have been captured in primeval forest Furthermore, in tropical Africa, there are very few large centers of population, as a rule, natives live in small villages In large towns, the installation of a pipe water supply is one of the most efficacious methods of *aegypti* control

The development of the newer insecticides has proved of great value to the sanitarian interested in yellow fever control Thus, DDT would appear to be almost ideal for the control of *Aedes aegypti*, applied as a residual spray to the walls of all houses or to the outside and the inside of household water containers at infrequent intervals, it will reduce the number of mosquitoes so significantly that this procedure alone is a very effective and inexpensive method of control The extensive use of a DDT spray is probably the method of choice in combating a severe aegypti-borne epidemic of yellow fever Marked reduction of adult mosquitoes should occur immediately, whereas experience has shown that antilarval measures require approximately 6 weeks to reduce the mosquito population below the critical level (Antunes, 1948)

Two strains of attenuated yellow fever virus are currently in use for human vaccination These are known as the French neurotropic and the 17D strains The French neurotropic virus is used extensively by the French in their West and Central African colonies (Peltier et al, 1940) The original French strain of yellow fever virus was isolated from a Syrian in Dakar in 1929 This is the strain which was first shown to be pathogenic for mice by intracerebral inoculation (Theiler, 1930). By serial passage, this virus became more pathogenic for these rodents but lost entirely its capacity for producing fatal visceral yellow fever in rhesus monkeys The method of vaccination as employed by the French consists in the use of this mouse-adapted virus

Other investigators, largely as a result of animal experiments, considered this strain too virulent for human use Consequently, a method of vaccination was evolved in which the subcutaneous inoculation of the French neurotropic virus was preceded by an injection of human yellow fever immune serum (Sawyer, et al, 1932). This method proved to be effective but cumbersome and impracticable for large-scale immunization Consequently, efforts were made to produce a strain more modified than the French neurotropic. This was achieved by prolonged cultivation of yellow fever virus in tissue culture This produced the 17D strain

For the production of vaccine, developing chick embryos are inoculated (Penna, 1956) After 4 days' incubation at 37° C. the embryos are harvested and reduced to a pulp, either in a ball mill or a Waring Blendor The infected chick-embryo juice, after the addition of some sterile distilled water, is then measured into ampules and desiccated while in the frozen state Before sealing, the ampules are filled with dry nitrogen gas Vaccine is stored in a refrigerator For use, the vaccine is reconstituted in the requisite amount of sterile salt solution, and 0 5 cc is injected subcutaneously As the virus in the vaccine is active, only one inoculation is necessary Experiments have shown that very minute quantities of active virus are capable of producing immunity in man (Fox et al, 1943), the minimum inoculum for successful vaccination has been set at 500 M L D (for mice) The reactions following vaccination usually are remarkably mild In approximately 5 per cent of persons there is a reaction on about the seventh day (Smith et al, 1938), this consists of malaise, headache, backache and a slight elevation of temperature, and, usually lasting about a day, it is seldom severe enough to interfere with a person's daily routine On rare occasions encephalitic symptoms have occurred following vaccination with 17D These cases occurred in infants who all recovered

without any sequelae (Stuart, 1956). Immunity, as determined by the demonstration of specific neutralizing antibodies, is manifest by the seventh to the ninth day after vaccination The titer of antibodies in persons vaccinated with 17D virus is, as a rule, low In fact, as evaluated by the standard protection test, there are always approximately 5 or 10 per cent of people whose sera, according to the criteria of the test, must be considered negative However, by the use of more delicate tests it can be shown that these are not truly negative but contain specific neutralizing antibodies, though in minimal amounts The duration of immunity following vaccination has not been determined. However, it is known that the number of persons showing antibodies is not significantly decreased after 6 years (Dick and Smithburn, 1949) There is some evidence that the immune response in children is less than in adults.

The method of vaccination used at present by the French consists of applying the vaccine suspended in a solution of gum arabic to the scarified skin (Peltier et al , 1940, Durieux, 1956). The vaccine is issued in the form of dried mouse brain infected with the French neurotropic strain of virus Suspension of the vaccine in gum arabic is made immediately before vaccination Often dried vaccinia virus is mixed with the gum at the same time, and the individuals are thus vaccinated against 2 diseases simultaneously, viz , yellow fever and smallpox. The development of specific antibodies to yellow fever following the French method of vaccination is better than that following the use of 17D However, the number of reactions is greater, being approximately 15 per cent Serious reactions are rare, but several very severe episodes have occurred following the use of the French neurotropic vaccine The most thoroughly studied of these episodes occurred in Nigeria Following the immunization of 42,000 Africans, 83 cases of encephalitis occurred within a 24-day period From the brain tissues of 4 cases that died of encephalitis 14. 14, 18 and 19 days after vaccination, strains of yellow fever virus were isolated which were indistinguishable in pathogenicity from the vaccine virus These studies indicate that on occasion the French neurotropic vaccine may produce a fatal encephalitis (Macnamara, 1955) However, it is noteworthy that the number of severe reactions are far less than the results of experiments on monkeys would have led one to expect. This method of vaccination has been used extensively in the African colonies The ease of administration and the cheapness of manufacture are of great importance.

The most conclusive evidence that vaccination is an effective prophylactic measure is supplied by the fact that, since the introduction of vaccination, no accidental cases of yellow fever have occurred in laboratory workers. Prior to the development of a vaccine, these infections were extremely common and in several cases even fatal Of similar nature is the observation that workers, investigating jungle yellow fever and using themselves as mosquito bait, on numerous occasions have isolated virus from *Haemagogus* mosquitoes caught in this manner. All such workers had been vaccinated and did not contract yellow fever. Observations such as this are good evidence that vaccination is highly efficacious.

To date, the results of mass vaccination have been satisfactory. In areas in Colombia where jungle yellow fever is prevalent and where efforts were made to vaccinate the entire population, fatal cases of yellow fever continued to occur But it is noteworthy that all these cases were in the small portion of the population which had not been vaccinated Vaccination is the only method available for the protection of persons exposed to the risk of jungle yellow fever In Africa, where anti-aegypti measures are to a large extent impracticable, mass vaccination is of particular value. In fact, this is the policy of the French government, which has embarked on a plan of vaccinating every person in their colonies every 4 years wherever yellow fever is present. The ease of manufacture and administration of their vaccine makes such a plan feasible.

Dengue

(SYNONYMS Break-bone fever, dandy fever, *denguero*, bouquet fever, giraffe fever, polka fever, 5-day fever, 7-day fever)

INTRODUCTION

Dengue is an infectious, mosquito-transmitted disease of virus etiology, characterized by fever, pain in various parts of the body, prostration, rash, lymphadenopathy and leukopenia

HISTORY

David Bylon is credited with the first description of an epidemic of this disease, which he called "joint fever" in Batavia, Java, in 1779 In 1780 Benjamin Rush described an epidemic in Philadelphia, Pa , under the name of "bilious remitting fever " During the 19th century, innumerable reports appeared of epidemics in subtropical and tropical regions throughout the world, and the name "dengue" was accepted for standard usage by the Royal College of Physicians of London in 1869 Some of the largest epidemics in history have occurred in the United States, Australia, Greece and Japan since 1920 During the 1922 epidemic in the U S it was estimated that between 1 and 2 million people had dengue in the southern states The Queensland-New South Wales epidemic of 1925-1926 attacked approximately 560,000 persons, and another large epidemic occurred in Australia in 1942 (Lumley and Taylor, 1943) During the 1927-1928 epidemic in Greece, the total number of cases probably exceeded a million From 1942 to 1945, the main ports of Japan had large, yearly epidemics of dengue with an estimated number of cases of from 1 to 2 million, the city of Osaka alone having one third to one half of its population attacked in 1944 (Sabin, 1952) Although only 84 090 cases of dengue were officially reported during the war years in U S. Army personnel, the total number of cases was undoubtedly much larger

authors also proved that *Aedes albopictus* is a true vector Ashburn and Craig, 1907, provided the first evidence that the etiologic agent of dengue is filterable and ultramicroscopic. The demonstration that dengue virus can produce inapparent infection in certain species of monkeys was followed by proof that certain monkeys may be infected *in nature*, and that the infection can be transmitted by mosquitoes from monkey to monkey as well as from monkey to man, which suggested that monkeys may constitute one of the links in the perpetuation of the virus in nature, Simmons et al , 1931 During World War II, extensive studies resulted in the demonstration of the very small size and other important

Sabin, 1952a). The ultimate adaptation and propagation of both types of dengue virus in very high titer in suckling mice, and the development of complement-fixing and hemagglutinating antigens, permitted further progress in studies on the diagnosis, the epidemiology, and the prevention of dengue (Sabin, 1955, 1956)

CLINICAL PICTURE

The clinical picture presented here is based on manifestations observed in natural cases of the disease and in several hundred human volunteers. The usual incubation period is from 5 to 8 days, although it may vary from 2 5 to 15 days, depending on the amount of virus introduced Prodromal symptoms of headache, backache, fatigue, stiffness, anorexia, chilliness, malaise and occasionally rash may appear 6 to 12 hours before the first rise in temperature In perhaps 50 per cent of the patients the onset is sudden, with a sharp rise in temperature associated with severe headache, pain behind the eyes, backache, pain in the muscles and the joints, chilliness and rarely a shaking chill. In typical cases, the fever (Fig. 53) persists for 5 or 6 days and usually terminates by crisis The temperature rarely exceeds 105° F., only occasionally returns to normal during the middle of the febrile period to give rise to the saddleback or diphasic type of curve, and quite frequently reaches its highest level during the last 24 hours of the febrile period Salicylates affect the fever in dengue and may give rise to very bizarre, spiking temperature curves At first, the pulse rate may rise proportionately to the temperature, but after the first day or two there is usually a relative bradycardia; an absolute bradycardia may occur during convalescence. Anorexia and constipation are common during the entire

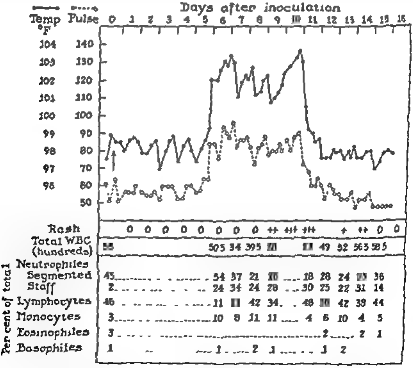

FIG. 53. Graphic representation of temperature and pulse rate of a human volunteer inoculated experimentally with the Hawaiian strain of dengue virus by means of the bites of eight infected *Aedes aegypti* mosquitoes; arrow indicates day on which the patient was bitten Time of appearance of rash is also indicated, as well as total and differential blood counts.

illness. Epigastric discomfort, colicky pain and abdominal tenderness may be seen. Altered taste sensations constitute a very common symptom early in the disease. The patient may become so weak and dizzy that he collapses when he tries to get out of bed. Photophobia, drenching sweats, sore throat, cough, epistaxis, dysuria, hyperesthesia of the skin, pain in the groin and the testicles, and delirium are some of the other manifestations occasionally encountered. A flushed appearance of the face, the neck and the chest, and a punctiform rash, especially over points of friction as at the back of the elbows and the front of the knees, may be seen early in the disease. The bulbar and the palpebral conjunctivae may be injected, the eyes are tender to pressure and painful on movement. Lymph nodes are frequently enlarged, but rarely the spleen. Although occasionally there may be sufficient edema about the fingers to interfere with closure of the hand, large joints present no abnormalities even when there is much subjective pain. Nuchal rigidity is absent even when the patient complains of a stiff neck.

The rash may be maculopapular or scarlatiniform, commonly appears on the third to the fifth day and rarely lasts more than 3 or 4 days. Usually it is seen first on the chest, the trunk and the abdomen and spreads to the extremities and the face. The incidence of this rash varies in different epidemics and also in the experimental disease caused by different strains of virus. Although itching, especially of the palms and the soles, is very common, desquammation occurs only rarely. Another type of eruption, occurring on the last day of fever or shortly after defervescence and consisting of very small petechiae over the dorsum of the feet and the legs, occasionally in the axillae, over the dorsum of the wrists, the hands and the fingers, and on the buccal mucosa and the hard and the soft palates, has been observed in the majority of human volunteers inoculated with the Hawaiian strain of virus (Sabin, 1952a) and in 20 per cent of the cases among American Naval personnel on a South Pacific island (Stewart, 1944). This petechial eruption, unlike the earlier maculopapular or scarlatiniform rash, does not blanch on pressure and fades after 1 to 3 days, leaving a transitory brownish discoloration. So-called Philippine hemorrhagic fever, an illness with extensive petechial rash predominantly on the limbs, epistaxis, gastrointestinal bleeding and shock, recently recognized among Filipino children and young adults, has been associated with infection by dengue virus (Hammon et al., 1958).

Changes in the blood leukocytes are not characteristic for dengue. During the first 24 hours the total number of white cells may be normal, but the lymphocytes show an absolute and relative decrease, while the number of neutrophils is increased by the appearance of immature forms. As the disease progresses, the total number of leukocytes drops, sometimes to as low as 1,500 cells per c.mm., due to a marked diminution in the neutrophils. The lymphocytes begin to increase in number as the neutrophils diminish, and toward the end of the febrile period and early in convalescence frequently constitute the major portion of the circulating leukocytes. The blood picture, as a rule, returns to normal within a week after defervescence. The urine is normal in most cases. The cerebrospinal fluid has been found to be normal in large numbers of patients with dengue, and reports to the contrary cannot be accepted without evidence for the correctness of the diagnosis.

The description given above applies to typical cases, but there is evidence, viz., recovery of virus from patients, that mild febrile illness of from 1 to 3 days' duration without rash may be dengue. Experimental studies on human volunteers have shown that reinfection with a different immunologic type of virus 2 to 3 months after a primary attack may give rise to malaise and slight fever for less than 24 hours, and mosquitoes feeding on such patients acquire the capacity to transmit the infection; furthermore, as the group immunity wears off, infection with a heterologous type of virus has been found frequently to cause febrile illnesses of 2 and 3 days' duration without rash. Since more than one immunologic type of virus has been recovered from the same region at the same time, reinfection with heterologous types of virus may be one of the causes for many of the atypical forms of the disease encountered during certain epidemics (Sabin, 1952a).

Convalescence from severe attacks may take several weeks and is characterized by

marked asthenia. *Occasionally, during* convalescence a disturbance *of vision due to* accommodative weakness or paralysis of the ciliary muscle may occur and persist for from 1 to 4 weeks. Although *there is doubt as to* whether dengue can be a primary cause of death, it has been *so reported during some* of the large *epidemics in* Australia and Greece. The case fatality rate in some *epidemics has* been estimated at 3 per 10,000 (MacCallum and Dwyer, *1927), but* in the recently recognized Philippine hemorrhagic fever, *apparently caused by* dengue virus, the case *fatality rate was 15 per* cent among *750* cases reported in Manila *(Hammon et al., 1958)* A high incidence of spontaneous abortion has *been reported* among women with dengue fever (Magara, 1942).

PATHOLOGIC PICTURE

Goldsmid, 1917, Photakis, *1929*, Catsaras, 1931 and Melissinos, 1937, have *reported on* fatal cases of what they *believed to be* uncomplicated dengue, and described degenerative changes in the liver, the kidneys, the heart or the brain, and hemorrhagic manifestations of varying extent in the endocardium, the pericardium, the pleura, the peritoneum, mucosa of the stomach and the intestines, *muscles*, skin and the central nervous system Local skin lesions caused by the intracutaneous injection of dengue virus, and the maculopapular and petechial eruptions *in human* volunteers were studied by biopsy (Sabin, *1952a*). The epithelium was *not involved*, and no inclusion bodies were found. The *chief* abnormality occurred in and about small blood vessels and consisted of endothelial swelling, perivascular edema and infiltration with mononuclear cells. In the petechial lesions extensive extravasation of blood, without appreciable inflammatory reaction, was observed.

EXPERIMENTAL INFECTION; HOST RANGE

Intracutaneous injection of 0 1 cc. to 0.2 cc. of human serum containing 10 or more minimal *human infective* doses(M I D) of dengue virus is followed after an interval of from 3 to 5 days by local edema and erythema, 1 to 4 cm *in diameter. Serum obtained from experimentally infected* persons within 24 hours after the first rise of temperature was found to contain a million human M.I.D of virus per cc. Ten M.I.D injected intracutaneously produced as severe an infection as *did 1 million M.I.D* Amounts of virus in the range of one M.I D produced: (*1*) typical attacks of dengue; (*2*) mild, short attacks without rash followed by complete immunity, or (*3*) no evidence of infection except a partial immunity. Undiluted infectious serum rubbed on scarified skin produced unmodified dengue Nasal instillation of 1 million or 100,000 M I D. resulted in a very mild disease in some human volunteers, while others suffered from a typical, unmodified attack. Nasal instillation of 10,000 M.I.D. produced neither disease nor immunity. Instillation of 200,000 M.I.D into the conjunctival sac produced typical dengue in one volunteer, while 10,000 M I D. produced neither disease nor immunity in another (Sabin, 1952a) A laboratory worker developed dengue 9 days after human serum containing unmodified dengue virus was accidentally squirted in his eye (Melnick et al , 1948)

Inapparent infection with dengue virus has been produced experimentally in the following species of monkeys: *Cynomolgus fascicularis, Cercopithecus callitrichus, Macacus fuscatus, Macacus philippinensis, Macacus rhesus, Cebus capucinus, Ateles geoffroyi, Ateles fusciceps, Alouatta palliata, Marikina geoffroyi, Saimiri orstedii*, and *Aotus trivirgatus*. Focal infiltrative lesions of the type seen in nonparalytic poliomyelitis have been found in the spinal cord of rhesus monkeys sacrificed 6 weeks after intracerebral injection of human dengue virus; neutralizing and complement-fixing antibodies appeared in these monkeys from 12 to 21 days after inoculation and persisted for many months (Sabin, 1950) An essentially inapparent infection has been produced in chimpanzees (Paul et al., 1948) with development of neutralizing and complement-fixing antibodies which persisted for at least 10 months (Sabin, 1950). *Dogs*, young hogs, rabbits, guinea pigs, adult white mice, white rats, hamsters and cotton rats inoculated with human dengue blood have shown no signs of infection Tests for inapparent infection in dogs, rabbits, young hogs, and guinea pigs have been negative. Suckling or older mice, which fail to develop clinical manifestations

of infection following intracerebral injection of human serum containing dengue virus, are, nevertheless, resistant to infection by the highly virulent mouse-adapted virus during the first days after receiving the former, as a result of interference, and during subsequent months, as a result of active immunity (Sabin, 1950, 1952a).

Several strains of dengue virus have now been adapted to mice and maintained in serial passage by the intracerebral route In the early passages a small and varying proportion of the inoculated mice show clinical evidence of the infection after incubation periods which vary from 5 to 35 days The mice exhibit motor weakness, flaccid paralysis of one or more extremities with or without signs of encephalitis The intracerebral titer may be no more than 10^{-1} to 10^{-2} after the first 10 to 15 passages and 10^{-4} to 10^{-5} after the first 40 passages, during the course of further passages in 2- to 3-week-old mice, the titer rises to a level of 10^{-5} to 10^{-6} with corresponding shortening of the incubation period The titer of virus depends upon the age of the mice in whose brains it is propagated If the mice are from 1 to 7 days old at the time of inoculation, their brains yield virus suspensions with intracerebral titers of 10^{-7} to 10^{-8} per 0 03 cc ($10^{9.5}$ to $10^{9.5}$ LD_{50} per Gm) upon titration in approximately 3-week-old mice However, even after many serial passages in newborn mice, the titer reverts to 10^{-5} to 10^{-6} after a single passage in 14-day-old mice (Sabin, 1950) In the early passages, only young mice were found suitable for intracerebral titrations, but after thorough adaptation of the virus old mice could also be used Histologic examination of the brain and the spinal cord of affected mice indicates that the primary attack is on the neurons By the use of virus that has had only 40 to 50 intracerebral passages, it has not been possible to infect 14-day-old mice by the intraperitoneal route The mouse-adapted dengue viruses tested thus far are not pathogenic for rabbits, guinea pigs, mature young cotton rats and hamsters, although newborn hamsters may be susceptible

Unmodified human virus and early passage levels of mouse-adapted virus inoculated intracerebrally in rhesus or cynomolgus monkeys produce an inapparent infection with only focal infiltrative lesions, chiefly in the brain stem and the spinal cord. Continued passage in mice leads to the emergence of virus particles that are more neurotropic for monkeys, so that intracerebral inoculation of higher passage levels of mouse-adapted virus frequently results in a severe paralytic disease that clinically and histologically may be indistinguishable from poliomyelitis With the type 1 virus (Hawaiian strain), no paralysis was observed in large numbers of monkeys inoculated with amounts varying from 1 to 100,000 mouse LD_{50} of the 15th to the 20th mouse passage virus, while the 118th mouse passage virus produced paralysis more often with smaller doses (5 of 15 monkeys receiving 400 to 40,000 LD_{50}) than with larger doses (1 of 15 receiving 4,000,000 to 40,000,000 LD_{50}) With the type 2 virus (New Guinea C strain) no paralysis was observed among large numbers of monkeys inoculated with 8 to 80,000,000 LD_{50} of the 18th to the 26th passage in mice, but paralysis associated with extensive neuronal lesions in the spinal cord, the brain stem and occasionally also the cerebral cortex occasionally followed inoculation of the same virus after 13 passages in trypsinized monkey kidney tissue cultures (Sabin and Sweet, quoted in Sabin, 1955 and unpublished studies) Neutralizing, complement-fixing and hemagglutinating antibodies develop in all rhesus monkeys inoculated with unmodified or mouse-adapted virus, but the C-F antibodies are of higher titer and persist longer after infection with the unmodified virus

ETIOLOGY

The diameter of the virus, as determined by filtration of highly infectious human serum through gradocol membranes, was found to be from 17 to 25 mμ The virus can be sedimented from human serum by centrifugation at 24,000 r p m for 90 minutes in an 8-inch rotor of a vacuum ultracentrifuge Examination with the electron microscope of preparations, purified by differential centrifugation, from highly infectious human dengue serum revealed dumbbell-shaped structures (700 mμ × 20-40 mμ) which were not found in preparations from normal human serum (Sabin, Schlesinger and Stanley, quoted in Sabin, 1952a) Reagan and Brueckner (1952) found

rods, 42 to 46 mμ in width and 175 to 220 mμ in length, in electronmicroscopic studies of ultracentrifuged suspensions prepared from the brains of mice inoculated with the 114th mouse passage of the same strain (Hawaiian), but not in similar preparations from normal mouse brains On the other hand, Hotta (1953) found only spherical particles measuring about 20 mμ upon electronmicroscopic examination of the mouse-adapted type 1, Mochizuki strain that had been partially purified by adsorption on kaolin and elution with NH_4OH The virus, in the form of human serum, has been preserved in the frozen state at −70° C. and in the lyophilized state at about 5° C. for at least 8 years. Human blood has been found to be infectious after storage in an ordinary refrigerator for several weeks. Dengue virus is very unstable, however, even at refrigerator temperatures in the absence of a suitable stabilizer Rabbit serum, heated at 56° C. for 30 minutes, diluted with an equal amount of saline is used for preparing brain suspensions of the mouse-adapted virus for optimum storage at −60 or −70° C, and 10 per cent heated rabbit serum saline must be used for preparing dilutions of virus for titrations For material that is to be inoculated in human beings, 5 per cent human albumin adjusted to pH 8, has been found suitable for storage, lyophilization and for preparation of dilutions

Dengue virus is readily destroyed by shaking with ether (Hotta and Evans, 1956a). The virus in human serum or in mosquito suspensions is inactivated by ultraviolet light or by 0 05 per cent formalin, but when so inactivated it failed to produce immunity

Earlier reports of cultivation of unmodified dengue virus in chick embryos were not substantiated by adequate proof and have not been confirmed With type 1 (Hawaiian) mouse-adapted virus of high titer at the 18th mouse-passage level, it was possible to obtain serial propagation in chick embryos, but the yield of virus was 1 millionth of that achieved in the brains of suckling mice. The type 2, New Guinea "C" strain (mouse passage 21), despite its high level of multiplication in the brains of suckling mice (10^{-7} to 10^{-8} per 0 03 cc.), completely failed to multiply in chick embryos (Sweet and Sabin, quoted in Sabin, 1955). The best-sustained multiplication in chick embryos was obtained with the type 1 (Hawaiian) virus after 101 passages in mice, but even after 88 egg passages, the yield of virus, which was present mostly in the brain, was still only 1/100 to 1/1,000 of that obtained from the brains of suckling mice (Schlesinger, 1951). The egg-passaged virus retained the increased neurotropism for monkeys exhibited by the 101st mouse passage virus used to initiate the cultures (Sabin, 1955).

Using the early mouse passage levels, it was possible to propagate both types of dengue virus in trypsinized rhesus kidney cultures, but while Sweet and Sabin (quoted in Sabin, 1955) observed no specific cytopathogenic effect, Hotta and Evans (1956b, 1956c) reported late cellular degeneration Extracellular dengue virus is rapidly destroyed at 37° C., and growth curves indicated that the maximum yield of virus was obtainable at 4 days (Sweet and Sabin, unpublished studies) In the early tissue culture passages the type 1 virus yielded not more than $10^{3.8}$ mouse LD_{50} per cc of culture fluid, while the type 2 virus yielded titers of 10^6 LD_{50} per cc; at the 13th tissue culture passage both types of virus yielded 10^6 to 10^7 mouse LD_{50} per cc of culture fluid, but still without cytopathogenic effect

The existence of at least 2 immunologic types of dengue virus was established by (1) active cross-immunity tests in human volunteers, (2) dermal neutralization tests with convalescent sera in human volunteers, (3) neutralization tests in mice with convalescent sera from human beings and rhesus monkeys, and (4) complement-fixation tests with convalescent sera of human beings and rhesus monkeys Human volunteers reinoculated with the same strain of virus proved to be completely immune 18 months after a single experimental infection Since the volunteers lived in nondengue areas, there can be no question of reinforcement of immunity by intercurrent, inapparent infection. The results of reinoculation with a heterologous immunologic type depended on the interval after the original attack During the first 1 to 2 months there was active immunity to heterologous as well as to homologous strains. That this effect is most likely due to a common

antigen and not to nonspecific resistance resulting from a preceding febrile illness was confirmed by the fact that phlebotomus fever convalescents exhibited no such immunity to dengue virus From 2 to 9 months after the initial attack, reinfection with a heterologous type, as a rule, resulted in a modified form of the disease which was of shorter duration, less severe and without rash By this method of comparison 4 of 7 human strains, i e , the Hawaiian and the New Guinea "A" strains, and 2 strains from India belonged to one immunologic type (type 1), while the other 3, New Guinea "B," "C" and "D" belonged to another (type 2) (Sabin, 1950)

Neutralization of mouse-adapted dengue virus by intracerebral tests in mice has been found to be a function of two factors (1) specific antibody which is heat-stable (56° C for 30 min) and (2) a nonspecific, complementlike, heat-labile, accessory substance which produces the maximum inactivation of the sensitized virus after incubation in vitro for 2 hours at 37° C. Thus, when dengue virus with a low mouse intracerebral titer (10^{-3} to 10^{-4}) was used, no neutralization was demonstrable, either when heated serum was used with incubation of the serum-virus mixtures or when fresh or frozen serum was used without incubation of the serum-virus mixtures When both fresh or frozen serum and incubation of the serum-virus mixtures were employed, the neutralization indices of convalescent sera varied with the mouse intracerebral potency of the virus used, indices of 100 to 300 were the rule with early mouse passage viruses having titers of 10^{-3} to 10^{-4}, as compared with 10,000 to 100,000 with virus having an intracerebral titer of about 10^{-7}. With virus of higher potency, the heated dengue antiserum can by itself yield neutralization indices of 100 to 500 However, when an accessory factor is supplied to such a mixture in the form of fresh or frozen, "normal" (i e., no effect on dengue virus per se), undiluted human or guinea pig serum (by preparing the virus dilutions in such serum), the neutralization index becomes 50,000 (Sabin, 1950) While the major neutralizing antibody is type-specific, there is also a group-specific antibody which yields lower titers and occurs in some individuals but not in others This is particularly true of sera from human beings and rhesus monkeys infected with the type 2 dengue viruses, the majority fail to neutralize the type 1 (Hawaiian) virus, while occasional individuals may yield titers of 50 to 500 (Sabin, 1950) Neutralizing antibodies for the Hawaiian type of virus have been found as early as 7 days after onset of fever and for at least 4 years (the longest period tested thus far) after a single experimental infection in human beings in nondengue areas (Sabin, 1950)

Potent complement-fixing antigens (CF) for both types of dengue virus have been prepared from the brains of suckling mice infected with the maximally adapted strains of virus Human beings and monkeys infected with one type of dengue virus develop CF antibodies not only for both types of dengue but frequently also for the West Nile, Japanese B, Murray Valley and yellow fever viruses (Sabin, 1950, 1956) In individuals, who have had no previous infection with the related viruses, the homotypic CF antibody is usually of higher titer than the heterotypic or heterologous antibodies and persists for a longer period Tests on human volunteers residing in areas where none of these viruses is endemic indicated that homotypic CF antibody can persist for at least 4 years after a single infection

Hemagglutinins for chick erythrocytes have been obtained from the brains of suckling mice infected with either type 1 or type 2 dengue viruses by extraction with M/64 borate—KCl buffer, pH 9, in saline Such preparations retain their activity for at least 4 months at 4° C , but are completely inactive after one or more cycles of freezing (dry ice) and thawing The optimum conditions for reaction with the erythrocytes and stability in certain ranges of pH and temperature vary with the type of virus and the number of passages it has had in mice Thus, freshly prepared hemagglutinin from the 19th-mouse-passage, type 2 virus (New Guinea C) with a titer of 1 640 at pH 6 7 at 4° C failed to react at 23° C at pH 6 5 to 6.9, which is optimum for the type 1 virus (Hawaiian) at both 23° C. and 4° C Specific hemagglutination-inhibition (H-I) antibody was readily separated from normal inhibitor in human, monkey and rabbit sera by precipitation with

acetone Dengue antisera, devoid of neutralizing antibody for the heterotypic virus, contain H-I antibody of similar or lower titer not only for the heterotypic dengue virus but also for the West Nile, Japanese B, St. Louis and yellow fever viruses (Sweet and Sabin, 1954a, Sabin, 1956) By means of the H-I test it has been possible to show that at least *15 distinct* viruses, including the 2 types of dengue, form an antigenically related group —the so-called Group B of the arthropod-borne viruses (Casals, 1957, and Chap. 14) The dengue viruses, as well as other members of the Group B viruses, also share two additional characteristics not possessed by other viruses: (1) their multiplication is depressed by a genetically controlled factor present in the PRI strain of white mice (Sabin, 1952b), and (2) they are inactivated by a nonantibody, antiviral factor in human milk (Sabin, 1953)

This group relationship between the dengue and other viruses is not associated with any significant, active cross immunity Human volunteers, immunized with the 17-D strain of yellow fever were not resistant to small amounts of dengue virus, although an interference phenomenon was observed when the interval between administration of these 2 viruses was 7 days or less (Sabin, 1952a) An interference phenomenon between dengue and yellow fever has also been demonstrated in rhesus monkeys and to a certain extent in *Aëdes aegypti* mosquitoes (Sabin and Theiler, quoted by Sabin, 1952a)

DIAGNOSIS

Dengue should be suspected when a disease, having the clinical characteristics described above, occurs in persons living in or having recently arrived from known endemic areas at a time when the specific mosquito vectors are especially prevalent Diagnosis is difficult in sporadic, atypical and primary cases but is relatively easy once the identity of an epidemic has been established Epidemics of febrile illnesses with rash closely simulating dengue can be caused by certain types of ECHO virus, which are ubiquitous, by the West Nile virus (Bernkopf et al, 1953), which is known to occur in the Middle East, certain parts of Africa and Asia, and by leptospira Denguelike illnesses in Africa may be caused by viruses that are not antigenically related to the dengue group of viruses, e.g., the Chikungunya virus first discovered during an epidemic in Tanganyika in 1952-53 (Theiler and Casals, personal communication)

Any attempt at a rapid identification of the causative agent involved in a denguelike epidemic should include intracerebral inoculation of mice with serum or heparinized blood obtained within 24 to 48 hours after onset of fever. West Nile virus is readily recovered in adult mice, and the dengue viruses are detected with great difficulty only in newborn mice. Mice, not older than 2 to 4 days of the so-called Swiss variety, should be inoculated intracerebrally with 0.02 cc. of undiluted blood or serum, and other litters should also receive the 1 10 and 1:100 dilutions in an attempt to circumvent possible interference by large concentrations of virus that is of very low pathogenicity for mice Some strains of dengue virus may paralyze a large number of mice within 9 to 21 days, while others may affect only an occasional mouse or none The brain and the spinal cord of affected mice is passaged intracerebrally in suckling and adult mice and intra-abdominally in suckling mice. A dengue virus may be suspected when only the intracerebrally inoculated suckling mice succumb, and identification must then be undertaken by neutralization with type-specific antisera and also by hemagglutination inhibition A hemagglutinating virus possessing the properties just mentioned, that is inhibited by both types of dengue antisera in the hemagglutination test but is not neutralized by them or only slightly so, may represent a new type of dengue virus When none of the originally inoculated mice succumbs, the presence or the absence of infection with dengue virus can be determined by an intracerebral challenge inoculation with 100 LD_{50} of the mouse-adapted viruses at 4 to 6 weeks (Sabin, 1956). Recently, dengue viruses have been isolated by this procedure directly from the blood of patients in Malaya (Smith, 1956a), Trinidad (Anderson et al., 1956) and the Philippines (Hammon et al, 1958).

Homotypic neutralizing and H-I antibodies appear within 7 days after onset of fever,

while the C-F antibodies appear a week or 2 later (Sweet and Sabin, 1954b) For a presumptive laboratory confirmation of the diagnosis in the individual patient during the course of a dengue epidemic, the H-I test is the test of choice because the convalescent phase serum specimen obtained within a day or two after defervescence already shows a rising titer of H-I antibody by comparison with the acute phase serum It is necessary to use both type 1 and type 2 dengue antigens for this purpose because the heterotypic response may be delayed or of lower titer. In any attempt at rapid identification of the cause of a denguelike epidemic, the H-I test can help only in indicating whether or not a Group B virus is involved, and West Nile virus is the only other member of this group that has produced epidemics of febrile illness with rash The neutralization test is the least affected by group antigenic relationships and can be used for resolving the identity or the type of virus involved in a given case or epidemic (Smith, 1956b)

TREATMENT

There is no specific therapy

EPIDEMIOLOGY

The most important facts in the epidemiology of the disease are that the virus is transmitted only by certain species of *Aedes* mosquitoes, and that human beings, certain spe-

known as *Aëdes hebrideus* (Mackerras, 1946) and *Aedes polynesiensis* Marks (Rosen et al, 1954) are the only proved vectors of the virus. Although circumstances obtaining on Espiritu Santo, New Hebrides, during the epidemic of 1942-1943 (Daggy, 1944) and in certain parts of New Guinea (Mackerras, 1946) strongly pointed to *Aedes hebrideus* as a vector under natural conditions, the opinion has been expressed that "the island form of *Aedes hebrideus* found in the New Hebrides does not appear to be a vector of dengue in nature under normal conditions" (Perry, 1948) *Armigeres obturbans* has been claimed as a vector (Koizumi et al, 1917), but, because the experiments were carried out in Formosa at a time when dengue was occurring, judgment is suspended *Culex fatigans* (*quinquefasciatus*) has been shown to be incapable of acting as a true vector. Experimental studies in the United States (Sabin and Jahnes, quoted in Sabin, 1952a) have

taeniorhynchus, Aëdes cantator, Anopheles punctipennis, Anoph quadrimaculatus and *Culex pipiens*. *Aedes aegypti* mosquitoes can acquire the infection from patients 6 to 18 hours before and for at least 3 days after the onset, Siler et al, 1926 A minimum extrinsic incubation period of 8 days, more usually 11 to 14 days, is required after an infective blood meal before the mosquitoes can transmit the infection, and under suitable conditions of temperature they can function as effective vectors for the rest of their lives, which may vary from 1 to 3 months or more Blanc and Caminopetros (1930) have shown that *Aedes aegypti* may remain infective for at least 174 days Very small numbers of mosquitoes suffice to transmit the infection, the experimental disease having been produced by the bite of 1, Simmons et al, 1931, or 2 mosquitoes, Siler et al, 1926 The virus is not carried from infected mosquitoes to succeeding generations through the eggs It has not been possible to obtain infected mosquitoes by leaving larvae in human serum containing 1,000,000 M I D. of virus per cc. (Sabin, unpublished studies) It is clear, therefore, that the disease is most likely to persist in those areas where the conditions are favorable for the survival of mosquitoes throughout the year, and for this reason Rogers and Megaw (1942) suggested that countries near the equator are probably the permanent reservoir of dengue The newborn human population in these equatorial regions may be enough to keep the cycle of infection going from year to year Although *Aedes aegypti* is strictly domestic in its habits, *Aëdes albopictus* can exist in the bush or the jungle and by keeping the infection going among susceptible monkeys, Simmons

fever

The availability of serologic tests has provided new tools for specific identification of the viruses involved in present and past epi-

demics and in mapping the endemic zones. Thus, the type 1 dengue virus has been incriminated as the predominant virus in the Hawaii epidemic of 1943-44, the extensive Japanese epidemics of 1944-45 (Sabin, 1952a), the epidemic of 1926-27 in Durban, South Africa (Kokernot et al, 1956), an outbreak in Malaya in 1954 (Smith, 1956b), and in the epidemics in Tahiti and other Society Islands of French Oceania in 1944 (Rosen, 1958a) An investigation, carried out in 1954, established that the extensive epidemic which occurred in Panama in 1941-42, was in all probability due to dengue type 2 virus, and that dengue was not endemic in the area and had not been introduced again since persons born after 1942 exhibited no serologic evidence of infection with dengue viruses (Rosen, 1958b) The monkeys inhabiting the forests of Panama have been shown to be susceptible to experimental infection with the dengue viruses (Rosen, 1958c), but there was no evidence of natural infection among them, and together with the very low incidence of dengue neutralizing antibodies among people residing close to the forests, there is no evidence for a jungle reservoir of type 1 or 2 dengue in Panama (Rosen, 1958b) On the other hand, dengue seems to continue to be endemic in Trinidad (Downs et al, 1956), and a dengue virus antigenically closely related to type 2 was recovered from the blood of a patient in 1953 (Anderson et al, 1956) *Aëdes aegypti* appears to be the only vector in both urban and rural areas, but the extent to which it is currently infested with certain types of dengue is unknown, since only 1 of 109 children under 10 years of age had neutralizing antibodies for type 1 dengue compared with an incidence ranging from 25 to 85 per cent among older individuals (Downs et al, 1956) Rosen (1958b) has indicated that available evidence strongly suggests that in the Western Hemisphere *Aedes aegypti* is the only vector for dengue and that the current campaign for eradication of this mosquito may lead to the total elimination of dengue from this part of the world

Serologic surveys in Malaya and Borneo (Smithburn, 1954; Sabin, 1955; Smith, 1956c) and in India (Smithburn et al, 1954) indicated that both type 1 and type 2 dengue viruses are highly endemic in these parts of Asia, although type 1 seems to be more prevalent. Smith (1958c) found neutralizing antibodies for type 1 dengue virus in about 25 per cent of Malayans below the age of 11 years, in 50 per cent aged 11 to 20, and in almost 100 per cent over 30 years of age; a certain number of persons had neutralizing antibodies only for type 2 dengue, but the precise incidence of infection with this virus was difficult to determine. During World War II, both type 1 and type 2 dengue viruses were active at the same time in New Guinea (Sabin, 1952a) Although Africa has long been regarded as an endemic area for dengue on clinical and epidemiologic grounds, there is as yet no specific virologic evidence of persistent dissemination of dengue viruses anywhere in Africa

In contrast with the negative findings in Panama, evidence of infection with dengue or with a closely related virus was found among mainly tree-living animals in Malaya (28 of 40 monkeys, 7 of 12 slow lorises, 9 of 45 squirrels, 2 of 28 civets) but in very few of a large number of ground-dwelling forest animals (Smith, 1958c) Smith (1958c), therefore, postulated (1) a possible dengue reservoir among tree-dwelling animals maintained by some mosquito or mosquitoes not biting at ground level; (2) *Aedes albopictus*, which is present in large numbers in the forest fringe and biting chiefly outdoors serving as the link between the forest and the rural dengue in man, and (3) *Aedes aegypti* as the main vector responsible for urban outbreaks.

CONTROL MEASURES

To prevent the recurrence of epidemics, it is necessary to maintain a constant vigil against the breeding of *Aedes aegypti* mosquitoes In regions like Hawaii where, in addition to *Aedes aegypti*, *Aedes albopictus* mosquitoes multiply unchecked outside of cities, the control of mosquito breeding presents an especially difficult problem (Usinger, 1944). It takes fewer mosquitoes to keep a dengue epidemic going than are required for the continued dissemination of yellow fever (Hanson, 1936). Antimosquito measures on airplanes and ships contribute to prevention but they cannot keep out a person who may be in the incubation period of dengue. In the face of an epidemic, individual measures directed against mosquito breeding in all sorts of containers in the immediate vicinity of homes, offices and factories, as well as the judicious use of DDT residual spray inside these buildings, must receive the greatest attention, while mass spraying from airplanes

may be useful in the attack on *Aëdes albopictus* breeding in the outskirts of the human community

The possibility of preventing dengue by vaccination first appeared when it was found that the type 1, Hawaiian strain, beginning with the 7th passage in mice, lost its capacity to produce the severe illness and protracted fever characteristic of the natural disease in human beings but retained the capacity to produce a rash and solid immunity to the unmodified virus (Sabin and Schlesinger, 1945) Blood taken at the time the rash first appeared in persons receiving the modified virus, and inoculated into susceptible human volunteers produced only the modified infection *Aedes aegypti* mosquitoes feeding on people inoculated with the 10th-mouse-passage virus acquired the capacity to transmit the infection but only in the modified form Extensive tests carried out on people inoculated with the 15th-mouse-passage virus indicated that *Aëdes aegypti* mosquitoes, which had fed daily on the experimental subjects for a period of 14 days after inoculation, were unable to transmit the infection even after prolonged extrinsic incubation periods Thirty-three human volunteers inoculated with vaccine prepared from early passages of the type 1 virus in 2- to 3-week old mice in doses ranging from 1 to not more than 100 mouse PD_{50} or LD_{50}, developed maculopapular eruptions of varying extent, while systemic symptoms were either absent or very mild, and all were found to be immune upon exposure to *Aedes aegypti* mosquitoes of proved infectivity or inoculation of large doses of unmodified dengue virus An attempt to prepare a combined dengue and yellow fever vaccine by lyophilizing a mixture of the two viruses was unsuccessful, since 5 of 7 volunteers subsequently exposed to dengue-infected mosquitoes were not immune (Sabin, 1952a)

After strains of the type 2 dengue virus had been propagated in high titer in the brains of suckling mice, tests in human beings with both the New Guinea "C" (Sabin, 1955) and New Guinea "B" strains (Schlesinger et al, 1956) in doses of 10^4 to $10^{6.4}$ mouse LD_{50} indicated that the mutant strains behaved like the type 1 modified virus Further work on the practical aspects of vaccination against dengue with the modified type 1 and type 2 dengue viruses established the following significant points (Sabin and Sweet, unpublished studies):

1. Only early passage level strains should be used, since variants that are more neurotropic for monkeys (although not more so than the 17D yellow fever virus) appear on continued passage in mice
2. The vaccine should be prepared from the brains of suckling mice, because: (A) there is either little or no multiplication in chick embryos, and (B) both types of virus (and especially type 2) after thorough adaptation to monkey kidney cultures were more neurotropic for monkeys than the mouse-passaged seed virus
3 The optimum diluent for lyophilization of vaccine is 5 per cent human albumin adjusted to pH 8 0
4 The administration of 10^4 or more mouse LD_{50} of the type 1 virus produces a higher incidence of transitory malaise and occasionally low febrile reactions for a period of 2 to 4 days
5. The simultaneous administration of equal amounts (about 10^4 mouse LD_{50}) of both types of dengue virus led to a suppression or marked delay of the type 1 antibody response in some individuals
6. For administration of the smaller doses that need to be given to avoid the higher incidence of febrile reactions and malaise, the lyophilized vaccine must be diluted in 5 per cent human albumin, adjusted to ph 8, and maintained at ordinary refrigerator temperature (not more than a few hours) up to time of inoculation; otherwise, the virus quickly deteriorates, and no immune response is obtained
7 Both types of vaccine administered separately produced enough heterotypic cross immunity for a period of at least 6 weeks to prevent the appearance of rash or other signs, when type 1 vaccine was given 6 weeks after the type 2, no type 1 antibody appeared, but when type 2 vaccine was given 6 weeks after type 1, antibody development was delayed but not prevented
8. The H-I antibody provides a quick, simple and reliable measure of the response to vaccination

The experimental studies carried out thus far suggest that the following procedure of vaccination may be attempted in the case of need in the face of an extensive dengue epi-

demic or for the protection of those moving into highly endemic areas:

1 Inoculate type 1 vaccine only in a dose of about 10^3 suckling mouse LD_{50}, this would be expected to produce some sort of rash, grading from minimal to extensive, [redacted] almost all, and some transitory slight muscle aching and soreness behind the eyes, usually relieved by acetylsalicylic acid, in about 60 per cent after an incubation period of 10 to 16 days This may be expected to provide not only long-lasting immunity to type 1 dengue, which is the most common cause of large epidemics, but also a transitory protection against the type 2 virus for a period of about 8 weeks.

2. Depending on circumstances, the type 2 vaccine, in a dose not exceeding 10^4 suckling mouse LD_{50}, can be administered next but not earlier than 8 to 10 weeks after the type 1.

In the face of an epidemic definitely known to be caused predominantly by a type 2 dengue virus, it would of course be advisable to use the type 2 vaccine first

Phlebotomus Fever

(SYNONYMS Sandfly fever, pappataci fever, 3-day fever, mosquito fever)

INTRODUCTION

Phlebotomus fever is a self-limited, nonfatal, phlebotomus-transmitted illness of virus etiology, characterized by fever, severe headache, pain in the eyes, conjunctival injection, malaise and leukopenia The term "sandfly fever," popularly used among English-speaking people, has not been accepted in international scientific literature because biting insects belonging to the genus *Culicoides* and having no relation to the disease under discussion are also called sandflies Pappataci fever, the popular name for the disease in Italy and the Balkans, has also failed to find general acceptance The name "phlebotomus fever," first suggested by Newstead, 1911, and stressing the most important fact about the disease, namely, its specific relationship to the insects of the genus *Phlebotomus,* has been used by many writers and seems to be the most appropriate for international usage.

HISTORY

Although Pick, *1886,* is generally credited with the first description of the disease as a clinical entity under the name of Hundskrankheit (dog disease—*apparently because* the conjunctival injection was so striking that the eyes resembled those of a bloodhound), Birt, *1913,* and Whittingham, *1924,* call attention to Sir William Burnett's account of Mediterranean fever during the Napoleonic wars in 1799, Pym's description of Bulam fever in Gibraltar in 1804, and the reports of other British military surgeons during the early *19th century* on *Malta summer febricula*

between the midges known as the pappataci flies (*Phlebotomus papatasi,* Scopoli) and the disease from which newly arrived Austrian troops suffered each summer, and led to the *classic experiments of the Austrian* military commission consisting of Doerr, Franz and Taussig, 1909. Phlebotomus Fever

(SYNONYMS: Sandfly fever, pappataci fever, 3-day fever, mosquito fever)

INTRODUCTION

Phlebotomus fever is a self-limited, nonfatal, *phlebotomus-transmitted illness of virus etiology*, characterized by fever, severe headache, pain in the eyes, conjunctival injection, malaise and leukopenia. The term "sandfly fever," popularly used among English-speaking people, has not been accepted in international scientific literature because biting insects belonging to the genus *Culicoides* and having no relation to the disease under discussion are also called sandflies. Pappataci fever, the popular name for the disease in Italy and the Balkans, has also failed to find general acceptance. The name "phlebotomus fever," first suggested by Newstead, 1911, and stressing the most important fact about the disease, namely, its specific relationship to the insects of the genus *Phlebotomus*, has been used by many writers and seems to be the most appropriate for international usage.

HISTORY

Although Pick, 1886, is generally credited with the first description of the disease as a clinical entity under the name of Hundskrankheit (dog disease—apparently because the conjunctival injection was so striking that the eyes resembled those of a bloodhound), Birt, 1913, and Whittingham, 1924, call attention to Sir William Burnett's account of Mediterranean fever during the Napoleonic wars in 1799, Pym's description of Bulam fever in Gibraltar in 1804, and the reports [illegible] during the

the popular belief that there was a connection between the midges known as the pappataci flies (*Phlebotomus papatasi*, Scopoli) and the disease from which newly arrived Austrian troops suffered each summer, and led to the classic experiments of the Austrian military commission consisting of Doerr, Franz and Taussig, 1909. By appropriate tests on human volunteers living in areas free from the disease, the commission proved that the etiology [illegible]

the vector. Being a constant problem to foreign troops stationed in endemic areas, the disease has been the subject of study by several British military commissions, Whittingham and Rook, 1923; Young et al., 1926, Shortt et al., 1935; and during World War II for the first time by American investigators (Sabin et al., 1944, Sabin, 1951; Hertig and Fisher, 1945).

More recent studies have resulted in the adaptation of at least 2 immunologically distinct types of the virus (Sicilian and Naples) to suckling and adult mice, with the conse-

quent development of neutralization, complement-fixation and hemagglutination-inhibition tests and the demonstration that the modified viruses had lost their capacity to produce disease in man but were still immunogenic (Sabin, 1955)

CLINICAL PICTURE

Observations on more than 100 cases of the experimental disease in human beings produced with different strains of virus are the basis for this description of the clinical manifestations of the malady The incubation period of 3 or 4 days in the average case may vary from 2 5 to 6 days, exceptional incubation periods, one each of 50 hours, 7 days and 9 days, have been seen, following intravenous inoculation, however, incubation periods of 42 to 44 hours are common. The onset of the disease is sudden in the majority of cases In some there may be a prodromal period characterized by malaise, giddiness, constipation and abdominal distress The following signs and symptoms may be encountered at the onset or sometime during the course of the disease, although some of them are frequently absent in otherwise typical cases frontal headache, burning sensation or pain in eyes, photophobia, backache, stiffness in neck and back, pains in joints and extremities, anorexia, nausea, vomiting, abdominal distress, alteration or loss of taste, constipation during the first few days and diarrhea during convalescence, sore throat,

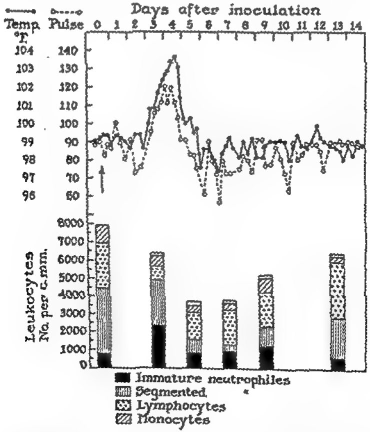

FIG 54 Graphic representation of temperature, pulse rate and blood picture of a human volunteer experimentally inoculated with the virus of phlebotomus fever, arrow indicates time of inoculation

epistaxis, chills or chilliness, profuse sweating, giddiness and weakness, especially during convalescence

The temperature usually reaches its peak, not over 104 5° F, within 24 or 48 hours after onset, and the febrile period in 85 per cent of the cases is 2, 3 or 4 days (Fig 54) Fevers of less than 1 day's duration and of 5 to 9 days' duration may occur The pulse rate is usually elevated in proportion to the fever on the first day of the disease, and thereafter returns to normal more rapidly than does the temperature A bradycardia may be present at the end of the febrile period and during convalescence Other physical findings are limited to an erythema of the face and exposed parts of the neck and the chest, conjunctival injection which is occasionally limited to the exposed portion of the ocular conjunctiva (Pick's sign), tenderness of the eyeballs, and congestion of the fauces, the soft palate and the posterior pharyngeal wall Rhinitis, tracheobronchitis, lymphadenopathy, and enlargement of the liver and the spleen are not a part of the disease Urticaria or erythema multiforme may be encountered occasionally, but a true rash as seen in dengue does not occur

Changes in the leukocytes are no different from those seen in dengue, infectious hepatitis and certain other infections with leukopenia. The characteristic finding on the first day of the fever is a total count within normal limits, a relative and absolute decrease in the lymphocytes accompanied by a relative and sometimes absolute increase in the neutrophils which is due to an increase in immature cells During the second or third day of fever, the number of lymphocytes begins to return to normal and for a few days thereafter may constitute from 40 to 65 per cent of the total count At the same time, the number of neutrophils begins to drop, and the immature cells increase to a point at which they usually outnumber the segmented cells The greatest drop in the total number of leukocytes may not occur until the end of the febrile period or after defervescence, but the marked shift to the left in the neutrophils and changes in the proportions of different types of cell at various stages of the disease are more important for diagnosis than is a single total leukocyte count. The urine is normal The cephalin-cholesterol-flocculation and phosphatase tests for hepatic damage are negative. The cerebrospinal fluid is normal in experimental cases, and there is no evidence that the pleocytosis reported in some outbreaks (Fleming et al, 1947) can be caused by the virus of phlebotomus fever.

The duration of convalescence varies with the individual and the climate; marked uncontrollable, transitory mental depression is encountered occasionally. Recurrences of the fever and symptoms during convalescence from the naturally acquired disease have been reported by several investigators and have also been observed from 5 to 7 days after the initial defervescence among 5 per cent of the experimentally inoculated volunteers (Sabin et al, 1944)

PATHOLOGIC PICTURE

There have been no fatalities among thousands of uncomplicated cases, and nothing is known of the pathologic changes produced by the virus.

EXPERIMENTAL INFECTION; HOST RANGE

No evidence of pathogenicity has been obtained with virus of proved infectivity for human beings after inoculation in the following lower animals by the intracerebral, intracutaneous, subcutaneous, intratesticular intranasal or intraperitoneal routes: young baboons (*Papio hamadryas*), grivet (*Cercopithecus griseoviridis*), vervet (*Cercopithecus aethiopis centralis*), red African hussar (*Cercopithecus patas*), *Macaca radiata* and *Macaca mulatta* (rhesus monkeys), 2- to 3-week old white mice, wild gray mice, cotton rats Egyptian desert rats (jerboas), Syrian hamsters, guinea pigs and rabbits The virus could not be demonstrated in the serum of rhesus monkeys 3 and 4 days after inoculation by subinoculation in human beings of proved susceptibility (Sabin et al, 1944) Six chimpanzees inoculated with human serum believed to contain the virus exhibited no clinical signs of infection. A slight febrile response in the 2 chimpanzees whose temperatures were being recorded could not be interpreted with certainty (Paul et al., 1948).

Virus has been recovered from the blood and the serum of experimentally inoculated human beings during the 24 hours preceding and the 24 hours following the onset of fever but not thereafter. The amount of virus in human serum, obtained even within a few hours after onset of fever, is relatively small, the maximum amount found in human tests with the Sicilian type of virus has been about 1,000 infective doses per cc. Furthermore, the amount of virus in the serum obtained from individual donors varied a great deal since in some instances even doses of 1 cc. did not produce disease (Sabin, 1951). Approximately 5 per cent of human adults, living in areas free of the disease, have been found to be refractory when the virus was inoculated by the intracutaneous or intravenous routes. In several simultaneous tests doses of virus, which usually produced the disease by the intracutaneous or intravenous routes, failed to cause fever, symptoms or leukocyte changes in from 50 to 75 per cent of the individuals inoculated by the subcutaneous or intramuscular routes. That an inapparent infection may have been produced in the latter human subjects is suggested by the fact that they were subsequently immune to large doses of virus injected by the intracutaneous or intravenous routes. On the other hand, persons inoculated intracutaneously or intravenously with amounts of virus too small to produce disease were not, with one possible exception, immune to the virus upon reinoculation of large amounts. The virus of phlebotomus fever does not give rise to skin lesions at the site of intracutaneous injection and differs in this respect from dengue viruses.

Work carried out since 1952 resulted in the adaptation to mice of the two known immunologically distinct types of virus, represented by the Sicilian and the Naples strains. The Sicilian strain in the form of infectious human serum had been stored in the frozen state for 9 years before it was successfully adapted to the brains of newborn mice. Three blind passages in 2- to 4-day-old mice at 7-day intervals yielded a virus that produced encephalitis after an incubation period of 11 to 12 days. After 10 passages in newborn mice at a time when the titer was already $10^{-3.4}$ per 0.01 cc., the virus still produced no clinical manifestations in weaned mice. Continued passage in the brains of newborn mice finally yielded a virus that produced encephalitis in newborn as well as weaned mice at a titer of 10^{-7} per 0.01 cc., i.e., 10^9 LD_{50} per Gm. of brain from infected newborn mice. Intracerebral inoculation of the highly pathogenic mouse-adapted strain produced a fatal encephalitis in 5- to 6-day-old rats, but neither clinical signs nor lesions in baby hamsters (18 to 20 Gm.), guinea pigs, rabbits or rhesus monkeys, since antibody appeared after this single inoculation, there may have been an inapparent infection in these animals. The mouse-adapted virus also lost its capacity to produce illness in human beings but still produced antibody and resistance to infection with the unmodified human virus.

A mouse-pathogenic variant of the immunologically distinct Naples strain was obtained from infected human serum after a single blind, intracerebral passage in newborn mice. The initial incubation period of 14 days was reduced to 8 days after 5 consecutive intracerebral passages in 2- to 4-day-old mice but despite a titer of $10^{-3.3}$ per 0.01 cc. it still produced no signs in 4-week-old mice. It was not until 35 consecutive intracerebral passages in newborn mice that the virus became regularly pathogenic for weaned mice, and in its 55th passage it yielded similar titers (still only $10^{-3.4}$ to 10^{-4} per 0.01 cc.) in newborn and weaned mice, although the incubation period was longer in the older mice. This fully adapted virus produced clinical manifestations in suckling and older mice also after nasal instillation but not after subcutaneous or intra-abdominal inoculation. Neither clinical signs nor lesions were observed in intracerebrally inoculated young rabbits, guinea pigs and baby hamsters, but neutralizing antibodies developed in the guinea pigs and the hamsters. Rhesus monkeys inoculated intracerebrally with either 10^5 or 10^4 mouse LD_{50} of the 30th passage virus all exhibited fever for about 10 days after an incubation period of 8 to 16 days, but no signs of paralysis, weakness or encephalitis. Histologically, these monkeys exhibited foci of interstitial infiltration and

epistaxis, chills or chilliness, profuse sweating, giddiness and weakness, especially during convalescence.

The temperature usually reaches its peak, not over 104.5° F., within 24 or 48 hours after onset, and the febrile period in 85 per cent of the cases is 2, 3 or 4 days (Fig. 54). Fevers of less than 1 day's duration and of 5 to 9 days' duration may occur. The pulse rate is usually elevated in proportion to the fever on the first day of the disease, and thereafter returns to normal more rapidly than does the temperature. A bradycardia may be present at the end of the febrile period and during convalescence. Other physical findings are limited to an erythema of the face and exposed parts of the neck and the chest, conjunctival injection which is occasionally limited to the exposed portion of the ocular conjunctiva (Pick's sign), tenderness of the eyeballs, and congestion of the fauces, the soft palate and the posterior pharyngeal wall. Rhinitis, tracheobronchitis, lymphadenopathy, and enlargement of the liver and the spleen are not a part of the disease. Urticaria or erythema multiforme may be encountered occasionally, but a true rash as seen in dengue does not occur.

Changes in the leukocytes are no different from those seen in dengue, infectious hepatitis and certain other infections with leukopenia. The characteristic finding on the first day of the fever is a total count within normal limits, a relative and absolute decrease in the lymphocytes accompanied by a relative and sometimes absolute increase in the neutrophils which is due to an increase in immature cells. During the second or third day of fever, the number of lymphocytes begins to return to normal and for a few days thereafter may constitute from 40 to 65 per cent of the total count. At the same time, the number of neutrophils begins to drop, and the immature cells increase to a point at which they usually outnumber the segmented cells. The greatest drop in the total number of leukocytes may not occur until the end of the febrile period or after defervescence, but the marked shift to the left in the neutrophils and changes in the proportions of different types of cell at various stages of the disease are more important for diagnosis than is a single total leukocyte count. The urine is normal. The cephalin-cholesterol-flocculation and phosphatase tests for hepatic damage are negative. The cerebrospinal fluid is normal in experimental cases, and there is no evidence that the pleocytosis reported in some outbreaks (Fleming et al., 1947) can be caused by the virus of phlebotomus fever.

The duration of convalescence varies with the individual and the climate; marked uncontrollable, transitory mental depression is encountered occasionally. Recurrences of the fever and symptoms during convalescence from the naturally acquired disease have been reported by several investigators and have also been observed from 5 to 7 days after the initial defervescence among 5 per cent of the experimentally inoculated volunteers (Sabin et al., 1944).

PATHOLOGIC PICTURE

There have been no fatalities among thousands of uncomplicated cases, and nothing is known of the pathologic changes produced by the virus.

EXPERIMENTAL INFECTION; HOST RANGE

No evidence of pathogenicity has been obtained with virus of proved infectivity for human beings after inoculation in the following lower animals by the intracerebral, intracutaneous, subcutaneous, intratesticular, intranasal or intraperitoneal routes: young baboons (*Papio hamadryas*), grivet (*Cercopithecus griseoviridis*), vervet (*Cercopithecus aethiopis centralis*), red African hussar (*Cercopithecus patas*), *Macaca radiata* and *Macaca mulatta* (rhesus monkeys), 2- to 3-week-old white mice, wild gray mice, cotton rats, Egyptian desert rats (jerboas), Syrian hamsters, guinea pigs and rabbits. The virus could not be demonstrated in the serum of rhesus monkeys 3 and 4 days after inoculation by subinoculation in human beings of proved susceptibility (Sabin et al., 1944). Six chimpanzees inoculated with human serum believed to contain the virus exhibited no clinical signs of infection. A slight febrile response in the 2 chimpanzees whose temperatures were being recorded could not be interpreted with certainty (Paul et al., 1948).

Virus has been recovered from the blood and the serum of experimentally inoculated human beings during the 24 hours preceding and the 24 hours following the onset of fever but not thereafter. The amount of virus in human serum, obtained even within a few hours after onset of fever, is relatively small; the maximum amount found in human tests with the Sicilian type of virus has been about 1,000 infective doses per cc. Furthermore, the amount of virus in the serum obtained from individual donors varied a great deal since in some instances even doses of 1 cc. did not produce disease (Sabin, 1951). Approximately 5 per cent of human adults, living in areas free of the disease, have been found to be refractory when the virus was inoculated by the intracutaneous or intravenous routes. In several simultaneous tests, doses of virus, which usually produced the disease by the intracutaneous or intravenous routes, failed to cause fever, symptoms or leukocyte changes in from 50 to 75 per cent of the individuals inoculated by the subcutaneous or intramuscular routes. That an inapparent infection may have been produced in the latter human subjects is suggested by the fact that they were subsequently immune to large doses of virus injected by the intracutaneous or intravenous routes. On the other hand, persons inoculated intracutaneously or intravenously with amounts of virus too small to produce disease were not, with one possible exception, immune to the virus upon reinoculation of large amounts. The virus of phlebotomus fever does not give rise to skin lesions at the site of intracutaneous injection and differs in this respect from dengue viruses.

Work carried out since 1952 resulted in the adaptation to mice of the two known immunologically distinct types of virus, represented by the Sicilian and the Naples strains. The Sicilian strain in the form of infectious human serum had been stored in the frozen state for 9 years before it was successfully adapted to the brains of newborn mice. Three blind passages in 2- to 4-day-old mice at 7-day intervals yielded a virus that produced encephalitis after an incubation period of 11 to 12 days. After 10 passages in newborn mice at a time when the titer was already $10^{-5.4}$ per 0.01 cc., the virus still produced no clinical manifestations in weaned mice. Continued passage in the brains of newborn mice finally yielded a virus that produced encephalitis in newborn as well as weaned mice at a titer of 10^{-7} per 0.01 cc., i.e., 10^7 LD_{50} per Gm. of brain from infected newborn mice. Intracerebral inoculation of the highly pathogenic mouse-adapted strain produced a fatal encephalitis in 5- to 6-day-old rats, but neither clinical signs nor lesions in baby hamsters (18 to 20 Gm.), guinea pigs, rabbits or rhesus monkeys, since antibody appeared after this single inoculation, there may have been an inapparent infection in these animals. The mouse-adapted virus also lost its capacity to produce illness in human beings but still produced antibody and resistance to infection with the unmodified human virus.

A mouse-pathogenic variant of the immunologically distinct Naples strain was obtained from infected human serum after a single blind, intracerebral passage in newborn mice. The initial incubation period of 14 days was reduced to 8 days after 5 consecutive intracerebral passages in 2- to 4-day-old mice but despite a titer of $10^{-3.8}$ per 0.01 cc. it still produced no signs in 4-week-old mice. It was not until 35 consecutive intracerebral passages in newborn mice that the virus became regularly pathogenic for weaned mice, and in its 55th passage it yielded similar titers (still only $10^{-5.5}$ to 10^{-6} per 0.01 cc.) in newborn and weaned mice, although the incubation period was longer in the older mice. This fully adapted virus produced clinical manifestations in suckling and older mice also after nasal instillation but not after subcutaneous or intra-abdominal inoculation. Neither clinical signs nor lesions were observed in intracerebrally inoculated young rabbits, guinea pigs and baby hamsters, but neutralizing antibodies developed in the guinea pigs and the hamsters. Rhesus monkeys inoculated intracerebrally with either 10^3 or 10^4 mouse LD_{50} of the 30th passage virus all exhibited fever for about 10 days after an incubation period of 8 to 16 days, but no signs of paralysis, weakness or encephalitis. Histologically, these monkeys exhibited foci of interstitial infiltration and

perivascular cuffing in the posterior and lateral horns of the spinal cord, medulla, midbrain, thalamus, hypothalamus, and only occasionally and minimally in the parietal and temporal cortex Despite the febrile episodes and lesions, only 1 of 9 monkeys developed a significant level of neutralizing antibodies Four human beings, inoculated intracutaneously with $10^{3.0}$ mouse LD_{50} of the 30th passage virus, exhibited neither fever nor clinical manifestations, and all developed neutralizing antibodies When these individuals were subsequently inoculated with unmodified human Naples virus that produced a moderately severe febrile illness in 2 simultaneously inoculated control individuals, 2 were entirely resistant, and 2 had a slight, transitory febrile response with about 10^2 mouse infective doses per cc. of serum at the time of the fever, which is 200 to 10,000 times less than was found in the serum of the controls (Sabin and Sweet, quoted in Sabin, 1955, also unpublished studies)

Ananyan (1953) reported that pappataci fever virus from certain areas in the U S S R multiplied in the blood, the lungs and the brain of young mice, guinea pigs, rats and rabbits either inapparently or with the production of "the clinical picture of the disease" The conclusions were based largely on the demonstration of complement-fixing activity of uncertain specificity in serum, lungs or brain of the inoculated animals. One of the strains that had been submitted to many passages in the brains of young mice (about 5 Gm), followed by many passages in the allantoic cavity of chick embryos, was used as a live vaccine against pappataci fever in the U.S S R. This vaccine was submitted by Dr. Ananyan for comparative studies, but it was neither pathogenic for newborn mice nor did it induce in them any immunity to challenge with the mouse-adapted Sicilian and Naples strains (Sabin, unpublished studies). Soshnikova (1954) reported the adaptation of pappataci fever viruses by intracerebral inoculation of 1- to 15-day-old mice with the production of a disease in mice that "follows the usual clinical course of pappataci fever" The relation of the pappataci fever viruses reported by investigators in the U.S.S R to those described here is as yet uncertain.

ETIOLOGY

By passing infectious human serum through gradocol membranes it was found that filtrates from membranes with an average pore diameter (A.P.D.) of about 200 mμ or more regularly produced the disease in human volunteers, while filtrates from membranes with an A.P.D. of 100 mμ or less did not (Sabin et al, 1944; Sabin, 1951). From these findings it was estimated that the diameter of the virus is not greater than 40 or 60 mμ but it could be smaller, since the concentration of virus in the human serum used for filtration was relatively low.

Recent studies with mouse-adapted viruses of higher potency indicated that the size of the virus is closer to 17 to 25 mμ. When a filtrate containing $10^{6.6}$ mouse LD_{50} per cc. of the Sicilian strain was passed through gradocol membranes of progressively smaller A P D., the virus passed through membranes with an A P.D. of 79 mμ but not through those with an A P.D of 50 mμ or less However, when only about 10^5 mouse LD_{50} per cc. were present in the suspension used for filtration, the virus failed to pass membranes with an A P.D. of 98 mμ. The Naples strain yielded the same filtration endpoints as the Sicilian strain when equivalent amounts of virus were filtered (Sabin and Sweet, unpublished studies).

The virus in the form of human serum has retained its infectivity after storage in a box containing solid CO_2 for at least 9 years, and for at least 8 years after storage in an ordinary refrigerator in the lyophilized state The mouse-adapted viruses suspended in heated undiluted rabbit serum can be similarly preserved (Sabin, 1955)

Although there are reports that unmodified human virus produces plaques on the chorioallantoic membrane or can be cultivated in chick embryos, the evidence is either inadequate or equivocal, and carefully controlled tests on human beings indicated that virus of known potency passaged in chick embryos in various ways produced neither disease nor immunity (Sabin, 1951). The high-titered, mouse-adapted Sicilian and Naples strains could not be propagated in chick embryos or in monkey kidney tissue cultures (Sabin

and Sweet, quoted in Sabin, 1955; also unpublished studies).

Multiple attacks of clinically similar illnesses during the same season or in subsequent seasons have led many to doubt that one attack of phlebotomus fever produces appreciable immunity. However, experiments on human volunteers residing in phlebotomus-free regions of the United States have shown that a solid immunity to reinfection with the same strain of virus is present as long as 2 years (longest period tested thus far) after a single experimental attack of the disease (Sabin, 1951) Three different strains of phlebotomus fever virus were obtained by human passage from natural cases occurring during 1943 and 1944 in troops stationed in the Mediterranean area (Sabin, 1951) Two of these, one from the Middle East and one from Sicily, proved to be identical by cross-immunity tests carried out 1 month, 4 months and 2 years, respectively, after primary attacks The third strain, recovered during an outbreak in Naples, possessed the characteristic properties of phlebotomus fever virus but was completely different immunologically from the other two Human volunteers proved to be immune to reinfection with the homologous Naples virus, developed typical, unmodified attacks of the disease after inoculation of the Sicilian virus within 2 months of the first infection Likewise, those who recovered from infection with the Sicilian virus suffered from unmodified attacks of the disease after inoculation with the Naples virus (Sabin, 1951) This complete lack of cross-immunity is unlike the picture exhibited by the multiple immunologic types of dengue virus in which a group relationship is manifested by cross-immunity tests during the first 1 or 2 months after the initial attack and by modified forms of the disease at later periods The Naples strain of virus, which is thus a completely distinct immunologic entity, has not yet been submitted to the ultimate test for a phlebotomus fever virus, namely, transmission by *Phlebotomus papatasi*

Both the Sicilian and the Naples mouse-adapted viruses propagated in the brains of newborn mice yielded complement-fixing (C-F) antigens of high potency which react specifically and in high titer with the respective hyperimmune sera prepared in mice. No C-F antibodies have been detected in the convalescent sera of human beings experimentally infected with the unmodified Sicilian strain, and titers of only 1 2 have been found with the Naples virus antigen in convalescent sera of those experimentally infected with the unmodified Naples virus

The methods which were successful in obtaining hemagglutinins from the dengue and other mosquito-transmitted viruses yielded only insignificant amounts from the brains of suckling mice infected with the Sicilian and the Naples viruses An inhibitor which could be extracted with alcohol but not with acetone or ether was the interfering agent In the case of the Naples virus it was also necessary to inoculate the mice with a 10^{-2} or 10^{-3} dilution of virus instead of with the more concentrated 10 per cent suspension in order to obtain a satisfactory yield of hemagglutinin Furthermore, unlike the hemagglutinins associated with the Group B viruses (dengue, etc. Chap 14) which do not react and are most unstable at 37° C, both the Sicilian and the Naples virus hemagglutinins react with chick erythrocytes optimally at 37° C between pH 5 5 and 6 5. Also, while the other viral hemagglutinins were unaffected by merthiolate (1:10,000), the Sicilian and the Naples virus hemagglutinins were completely inactivated. The following procedure may be used to obtain active hemagglutinins infected suckling mouse brains are frozen and thawed, extracted successively with 20 volumes of acetone, alcohol and ether, and the residue dried in vacuo and stored at 4° C, immediately before use the material is suspended in saline, centrifuged for clarification, and the supernatant liquid contains the active hemagglutinin Removal of nonspecific inhibitors from sera to be used for hemagglutination-inhibition (H-I) presented certain difficulties, since the usual procedure of precipitating the antibody with acetone was inadequate without further extractions of the precipitate with alcohol Seitz filtration was effective in removing the nonspecific inhibitors but it also reduced the amount of specific antibody. Tests with mouse hyperimmune sera yielded high titers of specific H-I antibody and also indicated that there was no antigenic relationship between the Sicilian and the Naples strains by the H-I and the C-F tests as well

perivascular cuffing in the posterior and lateral horns of the spinal cord, medulla, midbrain, thalamus, hypothalamus, and only occasionally and minimally in the parietal and temporal cortex Despite the febrile episodes and lesions, only 1 of 9 monkeys developed a significant level of neutralizing antibodies Four human beings, inoculated intracutaneously with $10^{5.9}$ mouse LD_{50} of the 30th passage virus, exhibited neither fever nor clinical manifestations, and all developed neutralizing antibodies When these individuals were subsequently inoculated with unmodified human Naples virus that produced a moderately severe febrile illness in 2 simultaneously inoculated control individuals, 2 were entirely resistant, and 2 had a slight, transitory febrile response with about 10^2 mouse infective doses per cc of serum at the time of the fever, which is 200 to 10,000 times less than was found in the serum of the controls (Sabin and Sweet, quoted in Sabin, 1955, also unpublished studies).

Ananyan (1953) reported that pappataci fever virus from certain areas in the U S S R multiplied in the blood, the lungs and the brain of young mice, guinea pigs, rats and rabbits either inapparently or with the production of "the clinical picture of the disease." The conclusions were based largely on the demonstration of complement-fixing activity of uncertain specificity in serum, lungs or brain of the inoculated animals One of the strains that had been submitted to many passages in the brains of young mice (about 5 Gm), followed by many passages in the allantoic cavity of chick embryos, was used as a live vaccine against pappataci fever in the U S.S R This vaccine was submitted by Dr. Ananyan for comparative studies, but it was neither pathogenic for newborn mice nor did it induce in them any immunity to challenge with the mouse-adapted Sicilian and Naples strains (Sabin, unpublished studies). Soshnikova (1954) reported the adaptation of pappataci fever viruses by intracerebral inoculation of 1- to 15-day-old mice with the production of a disease in mice that "follows the usual clinical course of pappataci fever." The relation of the pappataci fever viruses reported by investigators in the U S.S R. to those described here is as yet uncertain.

ETIOLOGY

By passing infectious human serum through gradocol membranes it was found that filtrates from membranes with an average pore diameter (A.P.D.) of about 200 mμ or more regularly produced the disease in human volunteers, while filtrates from membranes with an A P.D of 100 mμ or less did not (Sabin et al., 1944, Sabin, 1951). From these findings it was estimated that the diameter of the virus is not greater than 40 or 60 mμ but it could be smaller, since the concentration of virus in the human serum used for filtration was relatively low

Recent studies with mouse-adapted viruses of higher potency indicated that the size of the virus is closer to 17 to 25 mμ When a filtrate containing $10^{6.5}$ mouse LD_{50} per cc. of the Sicilian strain was passed through gradocol membranes of progressively smaller A.P D, the virus passed through membranes with an A P.D of 79 mμ but not through those with an A P D of 50 mμ or less However, when only about 10^3 mouse LD_{50} per cc were present in the suspension used for filtration, the virus failed to pass membranes with an A.P D of 98 mμ. The Naples strain yielded the same filtration endpoints as the Sicilian strain when equivalent amounts of virus were filtered (Sabin and Sweet, unpublished studies).

The virus in the form of human serum has retained its infectivity after storage in a box containing solid CO_2 for at least 9 years, and for at least 8 years after storage in an ordinary refrigerator in the lyophilized state The mouse-adapted viruses suspended in heated undiluted rabbit serum can be similarly preserved (Sabin, 1955)

Although there are reports that unmodified human virus produces plaques on the chorioallantoic membrane or can be cultivated in chick embryos, the evidence is either inadequate or equivocal, and carefully controlled tests on human beings indicated that virus of known potency passaged in chick embryos in various ways produced neither disease nor immunity (Sabin, 1951). The high-titered, mouse-adapted Sicilian and Naples strains could not be propagated in chick embryos or in monkey kidney tissue cultures (Sabin

and Sweet, quoted in Sabin, 1955; also unpublished studies).

Multiple attacks of clinically similar illnesses during the same season or in subsequent seasons have led many to doubt that one attack of phlebotomus fever produces appreciable immunity. However, experiments on human volunteers residing in phlebotomus-free regions of the United States have shown that a solid immunity to reinfection with the same strain of virus is present as long as 2 years (longest period tested thus far) after a single experimental attack of the disease (Sabin, 1951). Three different strains of phlebotomus fever virus were obtained by human passage from natural cases occurring during 1943 and 1944 in troops stationed in the Mediterranean area (Sabin, 1951) Two of these, one from the Middle East and one from Sicily, proved to be identical by cross-immunity tests carried out 1 month, 4 months and 2 years, respectively, after primary attacks The third strain, recovered during an outbreak in Naples, possessed the characteristic properties of phlebotomus fever virus but was completely different immunologically from the other two Human volunteers proved to be immune to reinfection with the homologous Naples virus, developed typical, unmodified attacks of the disease after inoculation of the Sicilian virus within 2 months of the first infection Likewise, those who recovered from infection with the Sicilian virus suffered from unmodified attacks of the disease after inoculation with the Naples virus (Sabin, 1951) This complete lack of cross-immunity is unlike the picture exhibited by the multiple immunologic types of dengue virus in which a group relationship is manifested by cross-immunity tests during the first 1 or 2 months after the initial attack and by modified forms of the disease at later periods The Naples strain of virus, which is thus a completely distinct immunologic entity, has not yet been submitted to the ultimate test for a phlebotomus fever virus, namely, transmission by *Phlebotomus papatasi*

Both the Sicilian and the Naples mouse-adapted viruses propagated in the brains of newborn mice yielded complement-fixing (C-F) antigens of high potency which react specifically and in high titer with the respective hyperimmune sera prepared in mice. No C-F antibodies have been detected in the convalescent sera of human beings experimentally infected with the unmodified Sicilian strain, and titers of only 1:2 have been found with the Naples virus antigen in convalescent sera of those experimentally infected with the unmodified Naples virus

The methods which were successful in obtaining hemagglutinins from the dengue and other mosquito-transmitted viruses yielded only insignificant amounts from the brains of suckling mice infected with the Sicilian and the Naples viruses. An inhibitor which could be extracted with alcohol but not with acetone or ether was the interfering agent In the case of the Naples virus it was also necessary to inoculate the mice with a 10^{-2} or 10^{-3} dilution of virus instead of with the more concentrated 10 per cent suspension in order to obtain a satisfactory yield of hemagglutinin Furthermore, unlike the hemagglutinins associated with the Group B viruses (dengue, etc Chap. 14) which do not react and are most unstable at 37° C, both the Sicilian and the Naples virus hemagglutinins react with chick erythrocytes optimally at 37° C between pH 5.5 and 6 5 Also, while the other viral hemagglutinins were unaffected by merthiolate (1:10,000), the Sicilian and the Naples virus hemagglutinins were completely inactivated. The following procedure may be used to obtain active hemagglutinins: infected suckling mouse brains are frozen and thawed, extracted successively with 20 volumes of acetone, alcohol and ether, and the residue dried in vacuo and stored at 4° C., immediately before use the material is suspended in saline, centrifuged for clarification, and the supernatant liquid contains the active hemagglutinin. Removal of nonspecific inhibitors from sera to be used for hemagglutination-inhibition (H-I) presented certain difficulties, since the usual procedure of precipitating the antibody with acetone was inadequate without further extractions of the precipitate with alcohol. Seitz filtration was effective in removing the nonspecific inhibitors but it also reduced the amount of specific antibody Tests with mouse hyperimmune sera yielded high titers of specific H-I antibody and also indicated that there was no antigenic relationship between the Sicilian and the Naples strains by the H-I and the C-F tests as well

as by the neutralization and the active cross-immunity tests. No antigenic relationship was demonstrable between the phlebotomus fever viruses and the other arthropod-borne viruses The Sicilian and the Naples viruses also differ from the Group B viruses (dengue, yellow fever, etc) in that the mouse-adapted variants killed adult "PRI" mice which are genetically resistant to the Group B viruses (Sabin and Sweet, quoted in Sabin, 1955; also unpublished studies).

Prior to adaptation of the viruses to mice, attempts to demonstrate neutralizing antibodies in the serum of known immune convalescents were successful only when mixtures of large amounts of convalescent serum and small amounts of virus were inoculated in human beings (Sabin, 1951) Although neutralizing antibodies are now readily demonstrated in tests with the mouse-adapted viruses of high potency the titers are still very low, and the low or negative results obtained with convalescent sera in C-F and H-I tests against potent antigens all indicate that the antibody response in this infection is of a very low order

DIAGNOSIS

The diagnosis of phlebotomus fever is generally made on clinical and epidemiologic grounds The disease is suspected when outbreaks of an illness with fever of short duration occur during the hot, dry season, especially among immigrants, tourists, or foreign troops in countries known to harbor *Phlebotomus papatasi* Differentiation from outbreaks of dengue is aided by the shorter duration of fever and the absence of rash and lymphadenopathy in phlebotomus fever Influenza is not common during the hot season and can be diagnosed by serologic reactions In localities where malaria is also prevalent and when, because of the pressure of events, antimalarial therapy may be administered in the absence of a positive smear, thousands of cases of phlebotomus fever have been erroneously diagnosed as malaria, Birt, 1915 (Sabin et al, 1944). Infectious hepatitis at the onset may simulate phlebotomus fever, but the subsequent appearance of jaundice or a positive cephalin-cholesterol test serves to differentiate the two conditions. In certain parts of Africa, yellow fever and Rift Valley fever may cause confusion, but their true identity can be established by recovery of the viruses of these diseases from patients and by neutralization tests. The clinical manifestations resulting from infection with many of the enteroviruses (ECHO, Coxsackie and polioviruses) may be most difficult to differentiate from those of phlebotomus fever.

Specific proof of infection with phlebotomus fever viruses can be obtained only by isolation of virus, which is now possible in suckling mice, and by the demonstration of development of antibody against the known types during convalescence. By intracerebral inoculation of 1- to 3-day-old mice with serum obtained early after onset of fever in suspected cases, more than 20 strains of phlebotomus fever virus were isolated in recent years in Egypt. The majority of these strains were immunologically very closely related or identical with the Sicilian type, and a few strains with the Naples type of virus C-F antibodies against the newly isolated as well as against the prototype strains were apparently more readily demonstrated in the sera of the naturally infected patients (R M Taylor, personal communication). Neutralizing antibodies may be demonstrated within 2 weeks after onset of fever. An indirect way of demonstrating the presence of one of the established types of virus in human serum consists of inoculating 1- to 3-day-old mice intracerebrally with 0 01 cc of serum and 4 weeks later challenging one group by an intracerebral inoculation of 100 LD_{50} of the Sicilian virus and another group with the Naples virus

TREATMENT

No specific therapy is available.

EPIDEMIOLOGY

According to present knowledge the disease is maintained in nature by passage from man to man through the medium of the intermediate host and vector, *Phlebotomus papatasi* Secondary cases do not arise by contact in the absence of the vector Although other species of *Phlebotomus*, e g, *perniciosus* and *caucasicus*, have been found in areas where

the disease has occurred, there is no experimental proof that they may act as vectors

Phlebotomus papatasi is a sand-colored, hairy midge, 2 to 3 mm long, somewhat less than 1 mm thick, easily recognized by the position of its 2 wings which are elevated and spread to form a V. The body of the female appears distended and red for some hours after a blood meal, and black for several days thereafter. Only the female bites and usually does so during the night and early hours of the morning. The site of a bite may or may not be marked by a reddish, pinpoint spot, and before a person becomes sensitive to the insects there is neither pain nor irritation beyond that of the initial stab However, from 1 to 2 weeks after the primary exposure to such bites, markedly inflamed, itching papules (2 to 3 mm in diameter, pink or red, sometimes vesicular) usually appear at almost all of the sites originally bitten and may persist for 4 or 5 days Once sensitization is established, such papules appear soon after bites The flies are most prevalent near the ground level, and, because of their small size and ability to squeeze through small apertures, ordinary screens and mosquito nets fail to exclude them Their flight is conducted as a series of short hops, alighting on stones and other obstacles in their approach to a house, and then, instead of entering at once, they tend to alight on the outer walls where they continue to hop about with relatively long pauses between hops After entering a house they continue to hop about on the walls and ceiling for some time before attempting to feed These peculiar habits of phlebotomus flies render them especially vulnerable to the residual action of DDT (Hertig and Fisher, 1945) Breeding places of the insects are difficult to demonstrate, but typical sites are found in loose soil, organic debris beneath stones, cracks in masonry, embankments, rubble, and dark, protected spots containing sufficient moist organic matter (Whittingham and Rook, 1923) The larvae are not aquatic and are killed by too much moisture They thrive during hot, dry seasons, and under optimum conditions 4 5 to 6 weeks are required for the eggs to develop into winged insects The life of the adult is relatively short in hot weather, and in the laboratory it lives no longer than 2 or 3 weeks An extrinsic incubation period of 7 to 10 days after feeding on a patient is known to be sufficient for transmission, but not enough work has been done to be certain that a shorter period will not suffice.

The geographic distribution of the disease is regarded as being limited to the areas harboring *Phlebotomus papatasi*, which include particularly those parts of Europe, Africa and Asia that lie between 20° and 45° north latitude. The disease is definitely known to occur in Sicily, Italy as far north as the Po Valley, along the Adriatic coast of Yugoslavia, Greece, Malta, Crete, Cyprus, Egypt, Israel, Jordan, Syria, Iraq, Iran, the coast of Crimea, the Azov and Black Sea littoral, provinces of central Asia in the U S S R, and the northwest and central provinces of India The disease is not known to occur in the United States, although man-biting species of *Phlebotomus, P diabolicus* in Texas and an undetermined species in the Okefenokee Swamp, Georgia (Johannsen, 1943), have been reported Whether or not these and other man-biting species of *Phlebotomus* in the western hemisphere are capable of acting as vectors of phlebotomus fever virus is not known. *Aëdes aegypti, Culex pipiens, Pulex irritans* (Sabin et al, 1944; Sabin, 1951) and bedbugs, Doerr et al, 1909, have been tested and found incapable of transmitting the infection.

Phlebotomus fever, unlike dengue, is not known to have invaded new territories. Large outbreaks have invariably occurred among troops or immigrants from countries free from the malady who had moved into endemic regions. Although the total number of cases of phlebotomus fever officially reported as hospital admissions in the U S Army during World War II was only 12,434, the actual number was undoubtedly much greater, thousands of cases having been reported as fever of unknown origin or as malaria (Sabin et al, 1944). Although the disease is practically never recognized among the native populations of endemic regions, it is obvious that the infection is acquired in infancy and childhood While it is clear how new susceptible subjects become available each year to aid in the perpetuation of the virus, it is not clear what the reservoir of the virus is during the late autumn and winter months when the phlebotomus flies are absent. The virus quickly disappears from the blood of human beings, and there is no evidence that it may be carried by lower animals Doerr and Russ, 1909, first suggested the possibility that the virus may be transmitted from one generation of infected *Phlebotomus papatasi* to another Whittingham, 1924, reported that *Phlebotomus papatasi* reared in the laboratory in England produced the disease in human be-

as by the neutralization and the active cross-immunity tests No antigenic relationship was demonstrable between the phlebotomus fever viruses and the other arthropod-borne viruses. The Sicilian and the Naples viruses also differ from the Group B viruses (dengue, yellow fever, etc) in that the mouse-adapted variants killed adult "PRI" mice which are genetically resistant to the Group B viruses (Sabin and Sweet, quoted in Sabin, 1955, also unpublished studies)

Prior to adaptation of the viruses to mice, attempts to demonstrate neutralizing antibodies in the serum of known immune convalescents were successful only when mixtures of large amounts of convalescent serum and small amounts of virus were inoculated in human beings (Sabin, 1951) Although neutralizing antibodies are now readily demonstrated in tests with the mouse-adapted viruses of high potency the titers are still very low, and the low or negative results obtained with convalescent sera in C-F and H-I tests against potent antigens all indicate that the antibody response in this infection is of a very low order

ings without previously feeding on infected persons, however, he believed that the larvae might have acquired the virus by feeding on the dejecta or dead bodies of adult flies Others, Young et al, 1926, noting that the flies did not die in their breeding grounds after oviposition and that the larvae showed no preference for feeding on the dead bodies of adult flies, maintained that infection of the insect probably occurred in their breeding grounds and suggested that the mites (*Trombidium hindustanicum* Hirst and *Raphignathus youngi* Hirst) which were found on about 4 per cent of adult phlebotomus flies might constitute the true reservoir of the virus Moshkovsky et al (1937), starting with the ova of thousands of flies which had been fed on patients, proved in a series of well-controlled experiments that certain of the adults raised from ova hatched away from their "parents" were capable of producing phlebotomus fever in human volunteers, that a virus caused the illness was established by serial passage in other human beings. The American commission (Sabin et al, 1944) was unable to produce the disease with offspring from flies of proved infectious capacity or from larvae which had ingested lyophilized virus, and concluded that transmission of the virus from one generation of flies to another is not a regular event The question of how the virus overwinters and what its true reservoir may be cannot be regarded as having been settled.

CONTROL MEASURES

Control measures are directed against the vector. DDT residual spray is effective against *Phlebotomus papatasi* (Hertig and Fisher, 1945) and should be used to control the vector in living quarters and breeding sites within a radius of 100 to 200 meters, which is the usual flight range for flies breeding near human habitations. Regular use of dimethyl phthalate and other effective insect repellents after sundown and upon retiring [illegible] the dis- [illegible] 944) [illegible] epidemics (Cullinan and Whittaker, 1943) were not infrequent in certain types of military installations, and separate wards, located from 300 to 600 meters away from other buildings, were considered desirable for patients with this disease.

Many reports have appeared in recent years of the success attained in the eradication of pappataci fever in various endemic foci of the disease in the U.S.S.R As a result largely of the systematic application of DDT and hexachlorocyclohexane in 1948 to 1952, the breeding of Phlebotomus was markedly reduced in Simferopol and the incidence of the disease in 1952 was believed to be about 800 times less in 1952 than in 1947 (Korolev et al, 1954). In 1956, the disease was regarded as being practically eradicated in Crimea and Ashkhabad, and vaccination was no longer used as a means of controlling pappataci fever in the U.S.S.R (V. M Zhdanov, personal communication). The actual virus content and the effectiveness of the live virus vaccine formerly used in the U.S.S.R. (Ananyan, 1953) is difficult to evaluate. While the mouse-adapted Sicilian and Naples strains possess properties that might make them useful as live virus vaccines, the problem of the practical development of such vaccines has not been pursued, chiefly because of the great effectiveness of DDT and related compounds in control of the vector.

severe aching of the muscles of the back and the legs are the prominent symptoms of onset; anorexia, nausea, vomiting, photophobia, muscle pains and hyperesthesia of the skin may be a part of the syndrome The temperature rises rapidly and is sustained from 102° to 104° F for about 2 days The pulse rate is increased correspondingly Usually on the third day a period of remission occurs that lasts 2 or 3 days During this time the temperature will be normal or even subnormal, but the patient is quite weak—exceptionally so for such a short illness The remission is followed by a relapse of 2 to 3 days The temperature may rise somewhat higher than in the first phase, and the febrile period may last a day or so longer Lloyd (1951) claims that well over 90 per cent of all cases show "this typical saddleback type of temperature curve" Meiklejohn (1957) has noted that while the great majority of cases follow the well-documented course of a "saddleback" or a "double hump" of fever, yet a number of exceptions do occur, and monophasic temperature curves are not too rare Occasionally, triple bouts of fever have been reported by others In addition, Meiklejohn states that he has accumulated considerable evidence of the occurrence of subclinical infections which were demonstrated only by neutralization tests on blood-serum samples

The white blood cell count falls to 2,000 or 3,000 cells per cu mm with the lowest count usually being found during relapse There is no exanthem with the disease, and the general physical examination is essentially negative except for the febrile condition and slight injection of the throat and the conjunctivae Following the recrudescence, patients frequently complain of great weakness which may last for several weeks The prostration is quite similar to that seen following influenza or dengue

No patients have been reported to have had the disease twice, and Florio et al (1944) showed experimentally that one attack of the disease confers a high degree of immunity to human volunteers Lloyd (1951) notes that on two occasions he has seen "punched-out ulcers" to form at the site of tick-bite. These are difficult to treat and apparently resemble the type of ulcer seen in scrub typhus Becker likewise noted that indolent ulcers occur frequently at the site of tick-bite and stated that they are not characteristic of ordinary secondary infection. Recently, Eklund et al (1955) have called attention to the fact that Colorado tick fever is not always the relatively mild or benign disease that the literature suggests Thus, virus was isolated from the blood of 5 children, all of whom showed signs of central nervous system involvement Encephalitis was suspected in 4 of the patients, and meningitis in the 5th One child was described as comatose, and 2 as disoriented and delirious More recently, Eklund (1957) reported that a young child, with evidence of encephalitis and a bleeding tendency, and from whom the virus of Colorado tick fever was isolated, died

Meiklejohn (1957) likewise has observed central nervous system involvement in 3 cases of Colorado tick fever. Of these 3, 2 showed a clinical picture which suggested an encephalitis similar to that seen with other viruses such as western equine encephalomyelitis or St Louis encephalitis The third case clinically resembled any of the comparatively benign viral meningitides with no real evidence of involvement of the brain itself This patient simply showed a stiff neck and back and a mild pleocytosis in the spinal fluid Present indications are that such cases of Colorado tick fever with involvement of the central nervous system are not too common However, it is seen from the above that the disease is not always mild.

PATHOLOGIC PICTURE

Nothing is known of the pathologic picture in man. In hamsters the only constant and significant lesions are found in the spleen (Black et al, 1947) Sections of spleens from infected animals stained with hematoxylin and eosin show alterations in the cellular type and arrangement of the follicular lymphoid tissue, with variations in the extent but not in the type of reaction Apparently, there is a reduction in the number of lymphoid cells in the central [illegible]

or complete disappearance of the normally well-defined margin This is replaced by a

Colorado Tick Fever

(SYNONYMS Mountain fever, tick fever, mountain tick fever, nonexanthematous tick fever, American mountain fever)

INTRODUCTION

Colorado tick fever is a nonexanthematous disease of man, characterized by a short-course and intermittent fever, and is the only tick-transmitted virus disease of man that is recognized in the Western Hemisphere.

HISTORY

Colorado tick fever has been described ever since white immigrants settled the Rocky Mountain region and undoubtedly was mentioned over a 100 years ago in medical reports of Army doctors stationed at various camps and forts in the Rocky Mountain area. Waggoner in 1850 described a series of typhoid fever cases among which were certain mild forms—possibly mountain fever Hygiene reports of the United States Army by Patzki, Towne, and Jaquette in 1875 contained many accounts of mild variants of malarial, typhoid or possibly undulant fever which fit the description of mountain fever. Toomey, 1931, reviewed these early reports and proposed the name *American mountain tick fever* for the disease However, Becker, 1930, was the first to report the condition as a separate clinical entity, to describe the disease clearly, to raise the question of the tick as a possible etiologic agent and to suggest the name it now bears, *Colorado tick fever*. In 1940, Topping et al, while conducting a clinical

that the disease is associated with the bite of the wood tick, *Dermacentor andersoni*. Florio et al. (1944) transmitted the disease serially in man and hamsters by parenteral injection of blood or serum and showed that the virus passes collodion filters. In subsequent papers they reported isolation of the virus from naturally infected ticks, *D. andersoni*, collected near Denver (1950a), and from *D. variabilis*, collected on Long Island, N. Y. (1950b). Koprowski and Cox (1946, 1947a, 1947b) adapted the virus to the mouse and the developing chick embryo. They showed that the virus was not related to the commonly known mosquito- or tick-transmitted viruses. Oliphant and Tibbs (1950) found 3- or 4-day-old Swiss albino mice suitable for isolating virus and reported the first isolations of Colorado tick fever viruses from patients who had been exposed outside of Colorado and Wyoming

CLINICAL PICTURE

From 4 to 5 days after exposure to ticks there is a sharp and clearly defined onset of the disease, and it is not unusual for a patient to be able to establish the exact time of onset The disease usually starts with chilly sensations and severe aching of the entire body. Fever, headache, deep ocular pain and

severe aching of the muscles of the back and the legs are the prominent symptoms of onset; anorexia, nausea, vomiting, photophobia, muscle pains and hyperesthesia of the skin may be a part of the syndrome The temperature rises rapidly and is sustained from 102° to 104° F for about 2 days The pulse rate is increased correspondingly Usually on the third day a period of remission occurs that lasts 2 or 3 days During this time the temperature will be normal or even subnormal, but the patient is quite weak—exceptionally so for such a short illness The remission is followed by a relapse of 2 to 3 days The temperature may rise somewhat higher than in the first phase, and the febrile period may last a day or so longer. Lloyd (1951) claims that well over 90 per cent of all cases show "this typical saddleback type of temperature curve" Meiklejohn (1957) has noted that while the great majority of cases follow the well-documented course of a "saddleback" or a "double hump" of fever, yet a number of exceptions do occur, and monophasic temperature curves are not too rare Occasionally, triple bouts of fever have been reported by others In addition, Meiklejohn states that he has accumulated considerable evidence of the occurrence of subclinical infections which were demonstrated only by neutralization tests on blood-serum samples

The white blood cell count falls to 2,000 or 3,000 cells per cu mm with the lowest count usually being found during relapse There is no exanthem with the disease, and the general physical examination is essentially negative except for the febrile condition and slight injection of the throat and the conjunctivae Following the recrudescence, patients frequently complain of great weakness which may last for several weeks The prostration is quite similar to that seen following influenza or dengue

No patients have been reported to have had the disease twice, and Florio et al (1944) showed experimentally that one attack of the disease confers a high degree of immunity to human volunteers Lloyd (1951) notes that on two occasions he has seen "punched-out ulcers" to form at the site of tick-bite These are difficult to treat and apparently resemble the type of ulcer seen in scrub typhus Becker likewise noted that indolent ulcers occur frequently at the site of tick-bite and stated that they are not characteristic of ordinary secondary infection Recently, Eklund et al. (1955) have called attention to the fact that Colorado tick fever is not always the relatively mild or benign disease that the literature suggests Thus, virus was isolated from the blood of 5 children, all of whom showed signs of central nervous system involvement. Encephalitis was suspected in 4 of the patients, and meningitis in the 5th. One child was described as comatose, and 2 as disoriented and delirious More recently, Eklund (1957) reported that a young child, with evidence of encephalitis and a bleeding tendency, and from whom the virus of Colorado tick fever was isolated, died

Meiklejohn (1957) likewise has observed central nervous system involvement in 3 cases of Colorado tick fever Of these 3, 2 showed a clinical picture which suggested an encephalitis similar to that seen with other viruses such as western equine encephalomyelitis or St Louis encephalitis The third case clinically resembled any of the comparatively benign viral meningitides with no real evidence of involvement of the brain itself This patient simply showed a stiff neck and back and a mild pleocytosis in the spinal fluid Present indications are that such cases of Colorado tick fever with involvement of the central nervous system are not too common However, it is seen from the above that the disease is not always mild

PATHOLOGIC PICTURE

Nothing is known of the pathologic picture in man In hamsters the only constant and significant lesions are found in the spleen (Black et al , 1947) Sections of spleens from infected animals stained with hematoxylin and eosin show alterations in the cellular type and arrangement of the follicular lymphoid tissue, with variations in the extent but not in the type of reaction Apparently, there is a reduction in the number of lymphoid cells in the central portion of the follicle, with the presence throughout the follicle of large pale-staining mononuclear cells, mingled with polymorphonuclear leukocytes and erythrocytes The periphery of the follicle shows a partial or complete disappearance of the normally well-defined margin This is replaced by a

ragged border of mononuclear cells, with occasional polymorphonuclear leukocytes and erythrocytes Giemsa stain shows both eosinophilic and basophilic intracytoplasmic inclusions present in the large mononuclear cells.

EXPERIMENTAL INFECTION, HOST RANGE

In the early passages, hamsters inoculated intraperitoneally with infectious blood remained normal in appearance, but starting with the 12th passage, some began to die, and thereafter a mortality rate of 25 to 50 per cent was common. Serial passage of the virus by parenteral injection of blood or serum through a series of 6 human volunteers did not alter the virulence of the virus for hamsters, although the incubation period in man was shortened to 3 days instead of 4 to 6 (Florio et al, 1946a) Dilute brown agouti mice or albino Swiss mice inoculated intracerebrally with mouse-adapted virus first show signs of paralysis of the legs, soon become prostrate and die, generally on the 5th to the 7th day. Mice 8 days of age are just as susceptible to intraperitoneal infection as are 28-day-old mice to infection induced by intracerebral inoculation. Resistance to virus inoculated intraperitoneally begins to be evident in 14-day-old mice Infected mouse-brain tissue is lethal for mice by the intracerebral route in 10^{-5} and 10^{-6} dilutions. Following intracerebral inoculation, mice, cotton rats, hamsters and opossums show virus in their blood, but sheep and rabbits do not; only the mice and the hamsters die of viral infection initiated by this route (Koprowski and Cox, 1947a). The virus grows in chick embryo tissue when the yolk sac method of inoculation is used The virus, which is found chiefly in the central nervous tissue of the chick embryo, reaches its maximum titer ($10^{3.3}$ to $10^{4.0}$ LD_{50}) in 4 or 5 days. Chick-embryo-propagated virus retains its virulence for mice and hamsters inoculated by the intracerebral route

Oliphant and Tibbs (1950) reported the primary isolation of 10 strains of Colorado tick fever virus by intraperitoneal inoculation of albino Swiss mice, 3 to 5 days old, using either blood serum or emulsified blood-clot from human beings suspected of having the disease and living in Colorado, Wyoming, Oregon or Utah. In 5 instances, signs of illness were seen in the first-passage mice within 5 to 8 days following inoculation Isolation of the other 5 strains required blind-passage technic in which infected brain tissue was transferred by intraperitoneal injection on the 5th day. All 10 strains were immunologically similar to the Florio strain first adapted to mice in 1946 by Koprowski and Cox. Great difficulties were experienced in adapting the established virus strains to young adult Swiss mice, but this was accomplished by using in successive passages mice that were 16 to 17 days old and 17 to 18

ETIOLOGY

The virus readily passes Berkefeld N and W candles and single Seitz EK pads By the use of collodion membranes, the diameter of the hamster-adapted virus was estimated to be 10 mμ (Florio, et al, 1946b), while the diameter of the mouse-brain-adapted virus was estimated to be 35 to 50 mμ (Koprowski and Cox, 1947a). The virus, when present in serum, is particularly stable, surviving for at least 3½ years in the ice compartment of an ordinary refrigerator or in a commercial deep-freeze unit. It is readily preserved by freezing and drying, may be inactivated by heating at 60° C for 30 minutes and apparently is relatively unstable in tick suspensions (Eklund et al, 1955).

The virus introduced in minimal amounts parenterally elicits an immune response in mice so that they can withstand subsequent intracerebral challenge with massive doses of mouse-brain virus (Koprowski and Cox, 1947b)

By cross-immunity tests in human volunteers, Florio et al (1946c) and Pollard et al (1946) showed that the viruses of Colorado tick fever and dengue are not related Neutralization tests carried out in mice (Koprowski and Cox, 1946; 1947a), or complement-fixation tests (De Boer et al, 1947) show that the virus of Colorado tick fever is different from the viruses of Russian spring-summer encephalitis, louping-ill, Venezuelan equine encephalitis, western equine encephalitis, eastern equine encephalitis, Japanese B encephalitis, St Louis encephalitis, lymphocytic choriomeningitis, rabies, yellow fever

and dengue fever, and also distinct from the rickettsiae of murine (endemic) typhus, Rocky Mountain spotted fever and Q fever.

DIAGNOSIS

A history of exposure to ticks, especially to *D. andersoni*, the biphasic or saddleback temperature curve, the symptomatology and leukopenia suggest the diagnosis of Colorado tick fever Neither acute phase nor convalescent sera show any significant Weil-Felix reaction in the presence of Proteus OX-19, OX-2, or OX-K antigens Specific complement-fixing antigens have been prepared from infected mouse brains, they do not give false positive reactions in the presence of positive-syphilitic sera (De Boer et al, 1947) A fairly close correlation is obtained in the complement-fixation and mouse-neutralization tests with human convalescent sera According to Eklund (1957) the neutralization test is a more useful diagnostic test in Colorado tick fever than in most virus diseases because antibodies tend to appear rather slowly Antibodies have been found absent as long as 26 days after onset of illness in cases where virus was isolated, in some cases only low antibody titers have been seen much later, but more often both complement-fixing and neutralizing antibodies do appear in good titer within 2 weeks They may remain demonstrable for at least 34 months

TREATMENT

There is no specific treatment Treatment is symptomatic

EPIDEMIOLOGY

As mentioned above, Colorado tick fever is the only tick-transmitted virus disease of man that is known in the Western Hemisphere Patients invariably give a history of having been in a tick-infested area 4 or 5 days previous to the onset of illness and in most cases have found a tick or ticks attached to their bodies The disease is most prevalent at the peak of the tick season The ticks are present in the late spring and early summer when the ground and the covering vegetation are moist Early cases may be seen in March and continue to increase to a peak in May and June Relatively few cases occur in July and later

wood tick, *Dermacentor andersoni*, the only species incriminated thus far in transmission of the disease to man. A possible exception to the above was noted by Eklund (1957) who stated that a virus isolation was made from *D occidentalis* ticks collected slightly outside the *D andersoni* area in Oregon The virus has also been isolated from other species of ticks collected within the *D andersoni* habitat area, such as *D parumapertus*, *D occidentalis*, *Otobius lagophilus* and *D. albipictus*, but no evidence exists as yet that any of these ticks are concerned in the transmission of Colorado tick fever to man (Eklund et al, 1955, Kohls, 1955; Philip and Hughes, 1953 and Philip et al, 1955) It is worthy of note, however, that neutralizing antibodies for Col-

macentor tick *D parumapertus* infests man, yet it is known that this tick, as well as *D andersoni*, infests blacktailed jackrabbits in some areas where the ranges of these two ticks overlap. Eventually this information may prove to be of more than academic interest (Philip et al, 1955)

Figure 55 (furnished by Dr Carl M Eklund, The Rocky Mountain Laboratory, U S. Public Health Service, Hamilton, Mont) shows the distribution of *D andersoni* and *D parumapertus* and the area in which Colorado tick fever has been isolated from human patients Virus has been isolated from lots of *D andersoni* collected in every state within its distribution with the exception of those collected in North Dakota, Nebraska and Arizona (Eklund, 1957) However, so few ticks have been examined from these states that the negative results are of no significance Virus has been isolated from ticks collected in several areas in western Washington, so that it is quite likely that the comparative absence of Colorado tick fever cases there may be due to lack of recognition of the disease Virus has also been isolated from ticks collected in Banff National Park, Alberta, Canada (Banfield, 1956), but no evidence of the disease has been reported there as yet Eklund et al (1955) stated that through the

year 1954 they had isolated Colorado tick fever virus from the blood of 193 patients exposed as follows California, 1, Colorado, 38, Idaho, 52, Montana, 16, Nevada, 34; Oregon, 26, Utah, 6; Washington, 1; and Wyoming, 19.

As would be expected, the majority of persons affected are those whose activities bring them in contact with ticks, such as cattlemen, foresters, sheepmen, fishermen and tourists

Florio et al (1950a) reported that the virus is transmitted transovarially by the adult female *D andersoni* They demonstrated transmitted virus in the larval, nymphal and subsequent adult life-cycle stages, although they were unable to detect virus in the eggs of the originally infected adults The same authors (1950b) also reported the isolation of 3 strains of Colorado tick fever virus from dog ticks, *Dermacentor variabilis*, collected on Long Island, N. Y.; hamsters were used in this work. Thus far, no human cases of Colorado tick fever have been reported from this area Pertaining to these questions, Eklund has recently pointed out (1957) that thus far he and his associates have secured no evidence of transovarial transmission of virus in *D andersoni* They believe that the virus is maintained by a cycle between immature ticks and small rodents. Furthermore, they have never isolated Colorado tick fever virus from *D variabilis*, although they have examined thousands of such ticks collected in both the eastern and the western United States Eklund et al (1955) have also attempted an estimate of the incidence of virus-carrying ticks in cer-

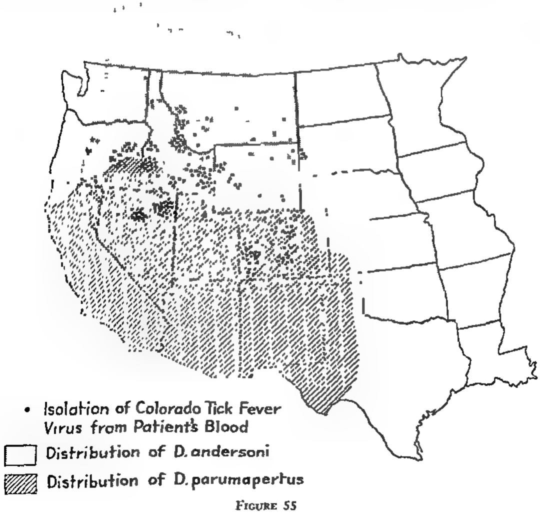

FIGURE 55

tain heavily infected areas of the Bitter Root valley of western Montana; the Boulder, Colorado, area and the Elko, Nevada, area In the Bitter Root valley, the incidence of virus-carrying ticks was estimated to vary from 1 3 to 10 3 per cent, in the Boulder area from 3.7 to 14 3 per cent or greater, and in the Elko area from zero to 6 5 per cent

Using the 3-day-old suckling-mouse technic of Oliphant and Tibbs (1950), Eklund (1957) has isolated at least 336 Colorado tick fever virus strains from patients' blood mailed in from various parts of the West during the past few years The following is the distribution of the isolations from blood samples prior to 1953, 63, 1953, 46, 1954, 87, 1955, 76 and 1956, 64 In addition, several hundred isolations were made from ticks collected in various parts of the West The increase in size of the area in which Colorado tick fever has been recognized does not reflect an increased effort to detect the disease in the field but rather increased attempts at the isolation of virus in the laboratory (Eklund [redacted] al, 1955) Philip and Hughes (1953) state that new laboratory technics may disclose that Colorado tick fever is the most widespread tick-borne disease of man in the western United States

CONTROL MEASURES

The prevention of Colorado tick fever depends primarily upon the avoidance of tick-infested areas and the early removal of any ticks that may become attached to the body It is also recommended that suitable clothing (high boots, leggings, or socks worn outside the trouser legs) be worn so that ticks will find it more difficult to become attached The arthropod repellants, dibutyl-phthalate and dimethyl-phthalate, have been suggested as being useful for impregnation of clothing to prevent the attachment of ticks (Joint OIHP/WHO Study-Group on African Rickettsioses, 1950) Koprowski and Cox (1947b) and Koprowski et al (1950) reported on the vaccination of a total of 24 human volunteers with active, chick-embryo-adapted virus Three of the 24 individuals probably were immune prior to vaccination and these showed no clinical reaction whatsoever Twenty showed enlarged, tender axillary lymph nodes adjacent to the site of inoculation, which appeared on the 6th or 7th day after injection and subsided within 24 to 48 hours. Twelve had a mild attack of illness which lasted from 2 to 5 days and resembled Colorado tick fever, except that there was only a single febrile response, and the onset and the disappearance of symptoms were more gradual than is usually seen in the natural disease One individual had circulating virus on the 6th and the 8th days after inoculation, and 2 others on the 6th day. All vaccinated individuals, including the 3 presumably immune, developed neutralizing antibodies The latter showed an earlier and greater serologic response Later, 5 of the inoculated individuals were challenged with a living, human strain of Colorado tick fever virus and apparently were immune. Thus far no practical applications of these findings have been made available

Miscellaneous Arthropod-Borne Virus Infections of Man

Although many of the arthropod-borne viruses can be classified in the A or B Groups, a considerable number show no such immunologic relationship The present chapter deals with viruses falling in this category which have been studied sufficiently well to justify their inclusion Other viruses which fall outside the A and B Groups are those causing phlebotomus fever and Colorado Tick fever (Chaps. 17 and 18)

RIFT VALLEY FEVER

(Synonym Enzootic Hepatitis)

Introduction

Rift Valley fever is an acute disease principally of sheep and cattle and is caused by a specific virus In man the disease is characterized by a short incubation period, acute onset, fever of several days' duration, prostration, pain in the extremities and the joints, abdominal discomfort and leukopenia The mortality rate is low, and the immunity following recovery is lasting Man is usually infected secondarily during the course of an epizootic in domesticated animals The natural disease has been reported only from Africa

History

During an extensive epizootic of an hitherto undescribed disease in sheep in the Rift Valley in East Africa in 1930, Daubney et al (1931) isolated a virus. Workers associated with these investigations contracted a short but severe febrile disease, and a similar clinical picture was common among the herders of the infected flocks The natural disease in sheep was ill-defined, consisting of listlessness, disinclination for food, and prostration The mortality was high in newborn lambs, death being due to acute liver necrosis, pregnant ewes aborted. Daubney et al (1931) showed that inoculation of a human volunteer with a filtrate of infected sheep tissue produced a disease similar to that observed in the herders Epidemiologic evidence pointed to a blood-sucking arthropod, possibly a mosquito, as a vector In 1951 a great epizootic of the disease occurred in South Africa during which it is estimated that 100,000 sheep and cattle died from the disease During this epizootic numerous human beings became infected In 1953 the disease again appeared in epizootic form, and the role of mosquitoes as vectors was clearly established

Clinical Picture

The incubation period is 5 or 6 days Onset is usually abrupt with malaise, chilly sensation and headache The symptoms increase rapidly, and the temperature rises to 102° to 104° F and is associated at times with chills Pain in the extremities and the joints may be extreme There is usually a feeling of discomfort in the epigastrium; definite tenderness or even abdominal pain may be present Nausea and vomiting are sometimes present The face is flushed, and the conjunctivae injected, photophobia is common The temperature curve is, as a rule, of the saddleback type, thus resembling that of dengue and yellow fever The disease usually lasts only a few days Convalescence is rapid, and recovery complete A fatal outcome is rare One of the most characteristic features is a marked leukopenia, which is due chiefly to a diminution of the polymorphonuclear leukocytes The urine, as a rule, is normal Complications are rare, the most important are ocular According to Schrire (1951), central serous retinopathy occurs, occasionally characterized by macular swelling and accompanied at times by small hemorrhages The onset varies from a few days to a few weeks after the pyrexial attack and is associated with a depression of visual acuity With the subsidence of the edema the eyesight generally returns to normal However, in some cases there has been a permanent impairment of vision Of the numerous laboratory infections that have occurred, only one was fatal, due to the development of venous thrombosis 45 days after the onset of the disease (Schwentker and Rivers, 1934)

Pathologic Picture

Human material not being available for study, knowledge of the pathologic picture of Rift Valley fever has been obtained by investigation of material from lower animals In sheep and other animals the most marked changes are observed in the liver (Daubney et al, 1931), focal necrosis, evenly distributed throughout the organ, and pinpoint hemorrhages are present In acute fulminating infections in lambs, the necrosis may be very extensive, destroying almost all the parenchymatous cells The architecture is destroyed, and there is an accumulation of phagocytic cells, chiefly polymorphonuclear leukocytes. The necrosis begins as a hyaline degeneration in a portion of the cell, rapidly extending to involve the whole cell, this process usually commences in the midzone of a lobule At first the degenerating cells are isolated and resemble a similar type of cell seen in livers infected with yellow fever virus and known as Councilman bodies Characteristic of the infection is the presence of intranuclear inclusion bodies Chromatin of the nucleus becomes marginated, and acidophilic material appears in the nucleoplasm. These inclusions are more homogeneous than those seen in yellow fever The pathologic changes observed in other organs are not distinctive. There is a tubular nephrosis; in the spleen and the lymph nodes toxic degeneration is present, and petechial hemorrhages are common in all the viscera Hemorrhagic enteritis has been described

Experimental Infection; Host Range

Sheep, goats and cattle are readily infected with the virus (Findlay, 1932) All monkeys tested to date can be infected, and a nonfatal illness is produced in rhesus, a febrile reaction in South American, and a silent viremia in African monkeys The virus is highly pathogenic for hamsters and is also pathogenic but not invariably lethal for ferrets, rats and other European and African rodents Suckling rats are more susceptible than are adults A species of African field rat (*Arvicanthis abyssinicus*) is readily infected with small inocula of virus and develops a moderately sustained viremia; most of these animals remain well, although a few succumb to the infection (Weinbren and Mason, 1957). Mice are particularly susceptible to the virus, death usually occurring within 2 to 3 days after inoculation In infected mice, the virus occurs in very high titer in the blood, being firmly bound to the red cells (Mims and Mason, 1956). Susceptible animals can be infected by any route, the resultant disease consisting of acute liver destruction Rabbits may develop a viremia of brief duration, while the

horse, pig, guinea pig, chicken, canary and pigeon are resistant

Mackensie and Findlay (1936) and Mackensie et al. (1936) produced a neurotropic strain by inoculating mice intracerebrally immediately after an intraperitoneal injection of immune serum By serial passage in such passively immunized animals, the virus lost to a considerable extent its viscerotropic affinities, so that it no longer produced death due to liver lesions when inoculated subcutaneously Inoculated intracerebrally, this modified virus produced a fatal meningoencephalitis in mice and monkeys A neuroadapted virus also produces a fatal disease on intracerebral inoculation into rats (Findlay and Howard, 1952) Smithburn (1949), by serial intracerebral passage in mice, produced a modified strain of Rift Valley fever virus with marked reduction in its hepatotropic affinites The subcutaneous inoculation of this neurotropic Rift Valley fever virus into newborn lambs or older sheep resulted in the development of immunity, although the virus was not demonstrable in the circulating blood nor did it cause any objective signs of infection Several vaccines have been developed for use in domestic animals (Henning, 1950) The accidental infection of a worker with virus which had undergone at least 300 passages in mice indicates that attenuation for man does not necessarily result from prolonged passage in these animals (Sabin and Blumberg, 1947)

The virus has been shown to multiply in tissue culture of the suspended cell type Both viscerotropic and neurotropic strains are markedly cytopathogenic in tissue culture for sarcoma cells of rat and mouse origin and also for fibroblasts of human embryonic, rat, mouse and swine origin (Takemori et al, 1954)

Etiology

The virus is readily filterable Its size as determined by filtration through gradocol membranes is 23 to 35 mμ, by ultracentrifugation, however, the particle size was found to be 50 mμ (Naude et al, 1954) It can be readily preserved in the lyophilized state

Complement-fixing and hemagglutinating antigens can be prepared readily In the latter, acetone-ether extraction of infective mouse serum has yielded excellent antigens (Mims and Mason, 1956) The virus of Rift Valley fever has no immunologic relationship with any other arbor virus, consequently, the serologic reactions following infection are remarkably specific

Diagnosis

Presumptive diagnosis of Rift Valley fever is made in individuals suffering from an influenzalike fever following contact with the virus in the laboratory or with naturally infected animals A positive diagnosis is made by isolation of virus from blood, this is achieved most readily by the inoculation of mice The virus isolated in this way is identified by typical lesions produced in the liver and by being neutralized by a Rift Valley fever immune serum Virus is present in the blood of human beings during the first 3 days of the disease In convalescence, the diagnosis can be made by demonstrating the development of specific neutralizing or complement-fixing antibodies Neutralizing antibodies have been demonstrated as early as 4 days after onset and as long as 12 years after recovery (Sabin and Blumberg, 1947) It is possible that the hemagglutination-inhibition test may prove to be a useful tool for the diagnosis of Rift Valley fever virus infections

A disease which epidemiologically and in its clinical manifestations in sheep, cattle and humans closely simulates Rift Valley fever is the infection caused by Wesselsbron virus (Weiss et al, 1956) The latter, however, is immunologically a member of Group B and completely unrelated to Rift Valley fever virus

Treatment

This is entirely symptomatic, as there is no specific treatment

Epidemiology

The naturally acquired disease has been [illegible]

Africa The disease is not contagious In-

fected animals can be kept in contact with normal animals without cross-infection taking place Daubney et al (1931) have shown that, in an infected region, sheep can be protected by screening at night From this, it may be concluded that the disease is transmitted by a blood-sucking insect active at night The cessation of an epidemic in a herd removed to the highlands is likewise evidence in favor of insect transmission Smithburn et al (1948), during their studies of the jungle vector of yellow fever in Uganda, isolated Rift Valley fever virus from 6 different lots of mosquitoes caught in the uninhabited Semliki Forest The mosquitoes involved included several species of the genus *Eretmapodites* and 3 of the genus *Aedes* By transmission experiments (Smithburn et al, 1949), it was shown that *Eretmapodites chrysogaster* can act as a vector of the virus. Gear et al (1955) in the studies of an epizootic in South Africa have found *Aëdes caballus* and *Culex theileri* the 2 most prevalent mosquitoes to harbor the virus Naturally infected *Aëdes caballus* were shown to be capable of transmitting the infection to experimental animals by bite *Aedes circumluteolus* has been found naturally infected in Tongaland (Kokernot et al, 1957a) It is apparent that very little definitive information is available concerning the epidemiology of the disease It is probable that domestic animals are infected by some blood-sucking arthropod Man as a rule seems to become secondarily infected during the course of an epizootic The finding of the virus in wild-caught mosquitoes of the Semliki Forest is highly suggestive of some virus cycle in wild animals Antibodies to Rift Valley fever have been found in wild-caught field rats, *Arvicanthis abyssinicus*, in Uganda indicating that these may play some role in the epidemiology and, as previously mentioned, this species is readily infected and develops a viremia How human beings are infected in the laboratory is unknown

Control Measures

Due to the numerous accidental laboratory infections, extreme precautions should be taken by all those working with the virus. There is no specific means of prevention of human infection at present, although vaccines have been developed for veterinary use (Henning, 1956). Arthropod abatement or eradication is perhaps indicated.

CRIMEAN HEMORRHAGIC FEVER

(Synonyms: *Acute infectious capillary toxicosis, hemorrhagic fever of Uzbekistan, of Turkmenia, of Tadjikistan*)

Within relatively recent times, a number of outbreaks of hemorrhagic disease of apparent viral etiology have occurred in various parts of the Soviet Union Various names were given to the outbreaks according to their geographic location, and more than 10 such names have been used in all. In the light of present knowledge, however, the situation appears to be less confusing, and Chumakov has proposed a classification which other Soviet scientists appear to accept (Zeitlenok et al., 1957). According to this concept, there are 3 clearly defined entities: hemorrhagic nephroso-nephritis (the epidemic hemorrhagic fever seen in U. S. military personnel in Korea), Omsk hemorrhagic fever and Crimean hemorrhagic fever The first 2 are dealt with elsewhere in the present volume (Chaps 14 and 20), and only Crimean hemorrhagic fever will be considered here The following description is based on a recent account by Prof M P Chumakov (1957) and upon the review of infectious hemorrhagic fevers in the U.S.S.R by Gajdusek (1953). Some of the information contained in the latter account appears to have been revised considerably since its publication. The first basic data on Crimean hemorrhagic fever were obtained in Crimea in 1944-46 by expeditions under the direction of Chumakov. Subsequent studies have been carried out, in particular those in Uzbekistan by Khodukin and his associates in 1948-1952

The clinical picture is that of an acute systemic disease with sudden onset Malaise, headache, generalized pains, weakness and gastro-intestinal disturbances occur early in association with the initial temperature rise. Fever persists for 5 to 12 days, showing, in the majority of cases, a diphasic course with a short afebrile period on the third to the fifth day Beginning on the fourth to the sixth day, hemorrhagic manifestations appear

consisting of pharyngeal enanthem, petechial rash on the trunk, purpuric skin hemorrhages, bleeding gums, epistaxis and, in severe cases, hematemesis and intestinal, uterine, pulmonary or renal bleeding. Mild or abortive cases occur in which bleeding may be absent. The blood picture characteristically shows a leukopenia which may change to a leukocytosis subsequent to severe hemorrhage. Thrombocytopenia and marked decrease in prothrombin are also characteristic. Crimean hemorrhagic fever is a rather severe infection, and convalescence is slow, but relapses or sequelae are not observed. The mortality rate is given as 2 to 8 per cent.

Pathologic examination of fatal cases discloses hemorrhages into the skin, subcutaneous tissue, lungs and other organs. Massive gastro-intestinal hemorrhage may be found. Degenerative changes in the liver and the ganglia of the autonomic nervous system are described.

Most of the experimental studies have been carried out in human psychiatric patients (the infection being used as a form of fever therapy). The causative agent shows little to no significant pathogenicity for a variety of laboratory and domestic animals. Virus is regularly found in the blood stream of febrile patients, and acute phase serum has been used for a complement-fixing antigen. The virus cannot be propagated serially in monkeys, although it causes a febrile reaction in them. It passes through the usual Seitz and Berkefeld filters and can be stored for long periods in the desiccated state. Using human subjects or monkeys in cross-immunity tests, the identity of various strains of the virus isolated from man and ticks has been established and the lack of relationship shown between this virus and those causing phlebotomus fever (pappataci fever) and Omsk hemorrhagic fever. Complement-fixation studies have also shown no relationship between the agents causing the Crimean and the Omsk diseases. There is, at present, no convenient method for making a specific diagnosis of the Crimean disease.

Convalescent serum is reported to be a successful therapeutic measure for seriously ill patients, treatment is otherwise symptomatic.

The disease has been demonstrated to occur in Bulgaria, the Crimea, the Astrakhan region and the middle Asiatic areas of the Soviet Union. It is a seasonal disease (spring-summer) and rural in distribution, affecting individuals working in or visiting the steppes. The incriminated vectors and reservoirs are *Hyalomma* ticks, in particular *H. plumbeum* and *H. anatolicum*, from which the virus has been isolated. The infection is not normally transmitted directly from man to man, but there has been a significant incidence of intrahospital infections in medical personnel as a result of contact with the blood of acutely ill patients.

Control consists of protection from tick-bite and the use of local tick-control measures.

CALIFORNIA ENCEPHALITIS VIRUS

Three strains of a previously undescribed virus were isolated in 1943 and 1944 by Hammon and Reeves from naturally infected mosquitoes in the San Joaquin Valley of California (Hammon and Reeves, 1952, Hammon et al., 1952, Reeves and Hammon, 1952). The strains were isolated from *Aëdes dorsalis* and *Culex tarsalis* mosquitoes, and a closely related virus was subsequently isolated from *Aedes trivittatus* mosquitoes in North Dakota by Eklund (Hammon et al., 1952). No isolations have been reported from man or other animals.

Hammon and Reeves (1952) reported 3 cases of encephalitis in California which, on serologic evidence, were possibly due to infection with this virus. One patient was an infant, 1 a child, and 1 a young adult. None of the cases was fatal, but the infant experienced a serious illness with possible residua. Serologic surveys in California have shown rather a high incidence (11%) of antibody in human inhabitants of the hot valley areas of the state. Presumably, most human infections are either inapparent or clinically unrecognized. A limited number of specimens obtained from other western states and from Japan were all devoid of detectable antibodies.

The virus is pathogenic for mice, cotton rats and hamsters by the intracerebral route but not for a variety of other animals tested. It reaches a titer of 10^{-5} to 10^{-6} in the brains of infected mice. Rabbits and ground

squirrels show a viremia following subcutaneous inoculation and become immunized. The virus multiplies in the chick embryo but is lethal for only a small proportion of those infected. The size is 60 to 125 mμ by gradocol membrane filtration. Hammon and Reeves reported a minor reaction, detectable by complement fixation, between St. Louis and Japanese B virus antigens and immune serum prepared against California virus. However, Casals (1957) was unable to confirm this finding and has shown that this virus is not a member of the A, the B, or the C Group of arthropod-borne viruses.

A rather high incidence of neutralizing antibody has been found in the sera of horses, cows, rabbits and ground squirrels in some parts of California. Four of 10 species of mosquitoes have been infected experimentally and transmission of the virus shown with *Aedes dorsalis* mosquitoes. No recent evidence is available concerning the role of this virus in human disease.

BWAMBA FEVER

During the course of investigations of jungle yellow fever in Bwamba county in Uganda, Smithburn et al. (1941) isolated 9 strains of virus from the blood of forest workers suffering from fevers of unknown origin. The 9 strains of virus were immunologically identical, and in each instance, serologic evidence was obtained of neutralizing antibodies in the convalescent sera of the donors. Isolation of the virus strains was obtained by the intracerebral inoculation of mice.

The disease was characterized by a sudden onset, fever, headache and backache. The symptoms persisted for about 5 to 7 days. There were no sequelae. Fatal cases have not been seen.

The virus of Bwamba fever multiplies in *Aëdes aegypti* mosquitoes infected by inoculation and can be transmitted from such mosquitoes by bite (Whitman, personal communication). It can be readily maintained by intracerebral passage in mice. On inoculation into *Cercopithecus* monkeys, a rather prolonged viremia occurs (Dick, 1953). The virus multiplies in but is not lethal for chick embryos following yolk-sac inoculation (Taylor, 1952) and it multiplies in and is cytopathogenic for various cell lines, including HeLa, in tissue culture (Moore, 1957). The virus size, as determined by gradocol membranes, is approximately 100 mμ (Smithburn and Bugher, 1953). Antibodies to the virus are found in the sera of individuals over a large area of Africa south of the Sahara desert, and Dick (1953) states that it is probably the most common virus disease in East, Central and West Africa. A high immunity rate has also been found in 6 species of African monkeys, including strictly arboreal ones. The common infection of man and arboreal animals implicates a flying insect as a probable vector (Dick, 1953). Limited surveys for immunity of residents in Asia and South America indicate that this infection is confined to the African continent.

An agent, the Pongola virus, immunologically very closely related to Bwamba, has been isolated on several occasions from wild-caught *Aedes circumluteolus* mosquitoes in the Tongaland region of South Africa (Kokernot et al., 1957b). Immunologically, these two agents are not related to any other arbor virus so far studied.

BUNYAMWERA VIRUS

Bunyamwera virus was first isolated and described by Smithburn et al. (1946). The original isolation was from a mixed pool of *Aedes* mosquitoes captured in the tropical rain forest in Bwamba, Uganda. Subsequent isolations of what appear to be the same agent were obtained from *Aedes circumluteolus* in Tongaland, South Africa (Kokernot et al., 1957a) and from the blood of a febrile child in the same area (Smithburn, personal communication).

Very little is known concerning the clinical manifestations in man infected with Bunyamwera virus. Its ability to cause a febrile reaction is indicated by the single human isolation. In addition, Southam and Moore (1951) inoculated 4 patients having inoperable malignant tumors with a late mouse passage strain of the virus. One succumbed to the malignant growth 3 days after inoculation, and 2 showed no signs of infection. The fourth developed a severe but nonfatal encephalitis attributable to the virus.

The virus is readily maintained by intracerebral passage in mice, producing a lethal infection and high brain titers It is pathogenic for suckling mice by either the intracerebral or the intraperitoneal route. The virus is markedly oncolytic for various mouse and rat ascites tumors in vivo (Koprowski, 1956) and grows well with complete cytopathogenicity in 6 different cell lines in tissue culture (Moore, 1957) Smithburn and Bugher (1953) reported the virus to be 70 to 105 mμ in diameter by gradocol membrane filtration but, on the basis of ultracentrifugation studies, Koprowski (1956) considered it to be much smaller (14 to 22 mμ). Clarke and Theiler (1955) were able to prepare a hemagglutinating antigen from suckling mouse serum, and subsequently a more satisfactory antigen has been prepared by acetone extraction of suckling mouse brain homogenized in sucrose solution By HI and CF tests the Bunyamwera virus is not related immunologically to any other arthropod-borne virus However, Weinbren et al (1957) have presented evidence for some immunologic relationship with a new agent, Simbu virus, recently isolated from *Aedes circumluteolus* in Tongaland, South Africa

Antibodies to Bunyamwera virus have been found in sera from residents of Uganda, Tanganyika, Nigeria (Dick, 1953) and Tongaland (Kokernot et al, 1956) in Africa Limited immunity surveys indicate that human infections with this virus occur in other tropical regions, such as the Amazon valley in South America (Causey and Theiler, 1957) and Malaya and Borneo in Asia (Smithburn, 1954)

GROUP C ARTHROPOD-BORNE VIRUSES

In recent years a large number of virus strains have been isolated in the Amazon rain forest near Belem by Dr O R Causey, director of the Belem Virus Laboratory, Brazil. Isolations have been obtained from the blood of human beings suffering from fevers of unknown causation, from the blood of sentinel monkeys and from wild-caught mosquitoes A large number of the strains are immunologically related to each other but not to any other arthropod-borne viruses These viruses have been studied both by Causey and by Casals and Whitman in the Rockefeller Foundation Virus Laboratories in New York. Although obviously related, these agents are not all identical At least 3 distinct immunologic types can be separated These have been named Marituba, Oriboca and Apeú These agents clearly form an immunologic group and consequently have been designated as Group C by Casals (1957) (Chap 12)

Very little is known so far concerning the clinical aspects of infection with Group C agents beyond the fact that the human isolations have been made in association with febrile illnesses

Viruses of the C group multiply in *Aedes aegypti* mosquitoes, and such mosquitoes can be infected by feeding on experimental animals and can transmit the virus by bite (Whitman, personal communication) The viruses of the group are highly pathogenic for suckling mice, both by intracerebral and peripheral routes of inoculation They show a variable pathogenicity for adult mice and are not lethal for chick embryos Although a moderate virus titer is found terminally in the brains of infected suckling mice, a higher titer is found in blood, and at least one member of the group shows a significantly higher infective titer in liver than in brain Hemagglutinating antigens have been prepared for many of the strains by acetone extraction of suckling mouse serum Complement-fixing antigens are best prepared from infected suckling mouse liver The separation of the agents into distinct species has been made largely by H-I test, these results being, in general, in good agreement with those obtained by neutralization tests With one exception, studies carried out so far by CF tests suggest that there is one complement-fixing antigen common to the C group so that different members cannot be distinguished from each other by this technic

Little information is yet available concerning the incidence of human infection with Group C viruses However, limited serologic surveys with the Oriboca agent indicate that immunity is quite prevalent in residents of the Amazon valley. H-I tests with human sera from Africa indicate that Group C virus infections probably occur on that continent also

OTHER UNGROUPED VIRUSES

Four additional viruses which have not been found to be related to other known agents have been isolated, described and named These are Anopheles A, Anopheles B and Wyeomyia isolated from mosquitoes in Colombia by Roca-Garcia (1944) and Turlock virus isolated by Lennette et al (1957) from mosquitoes and birds in California. At the present time there is not sufficient information concerning the role of these viruses in human infections to justify their further description here.

Hemorrhagic Fever

(SYNONYMS Epidemic hemorrhagic fever, hemorrhagic nephrosonephritis, Far Eastern hemorrhagic fever, Yaroslavl hemorrhagic fever)

INTRODUCTION

Hemorrhagic fever is an acute infectious disease characterized by physiologic and pathologic disturbances of the vascular system These include capillary dilatation with plasma leakage, proteinuria, petechial hemorrhages and hypotensive shock Toward the end of the first week, about 80 per cent of patients begin their recovery. The remainder have a stormy course with shock, renal insufficiency, marked fluid and electrolyte imbalances and sometimes secondary bacterial complications The mortality is about 5 per cent

The etiologic agent which is filterable can be maintained by serial passage in human beings, who develop typical disease, but it has not yet been established in laboratory hosts The agent presumably causes an enzootic disease in wild rodents and is transmitted in nature by an arthropod vector.

HISTORY

The disease was recognized by Japanese and Russian investigators about 2 decades ago in the environs of the Amur River separating Manchuria and Eastern Siberia (Kitano, 1944; Smorodintsev, 1944). During the Korean War it was an important military problem, being responsible for several thousand cases among United Nations troops (TB Med 240, 1953) More recently, patients with this malady have been reported in several parts of European U S S R (Chumakov et al, 1956, Chumakov, 1957), particularly in the Yaroslavl Region of the Volga Basin A number of other diseases resembling that under discussion have been described during the last decade in Europe and Asia Two of these, Omsk hemorrhagic fever and Kyasanur Forest disease, which are caused by tick-borne viruses of the Russian spring-summer encephalitis group, are discussed in Chapter 19. The others are reviewed elsewhere (Gajdusek, 1953)

CLINICAL PICTURE

Following an incubation period of about 2 weeks, the illness begins abruptly with high fever, chills, prostration, headache, backache and anorexia. Physical findings are limited initially to facial flush and injection of the conjunctivae and the palate. Petechiae appear about the 3rd day, followed promptly by the pathognomonic severe proteinuria The febrile phase usually ends about the 5th day, but manifestations of capillary leakage, including a rising hematocrit, increase during the hypotensive phase which persists for several days The capillary abnormalities begin to regress during the oliguric phase which follows and disappear with the onset of diuresis about the 10th day (TB Med 240, 1953; Earle et al, 1954).

The hypotensive and oliguric phases of the disease are particularly hazardous in the severely ill. In the former, shock occurs with hypotension, decreased cardiac output, reduced circulating blood volume and dilated peripheral capillaries which have reduced flow rate, vasomotor activity and responsiveness to norepinephrine. Certain patients, during the period of resorption of extravascular fluid early in the oliguric phase, develop the syndrome of "relative hypervolemia" with hypertension, high cardiac output, high blood volume, normal or low peripheral resistance, and metabolic acidosis. Acute renal failure with its usual manifestations may develop during the oliguric phase (Entwisle and Hale, 1957, Greisman, 1957).

Leukocytosis of 10,000 to 20,000 with many immature granulocytes usually reaches a peak by the end of the first week. Thrombocytopenia with counts below 100,000 occurs in half the patients. Renal clearance tests show slightly increased values early in the febrile phase, followed by a rapid decrease

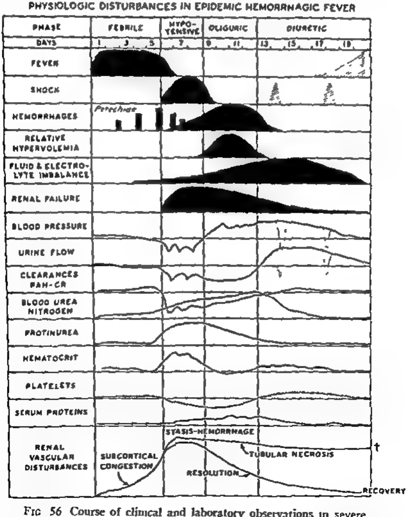

FIG. 56. Course of clinical and laboratory observations in severe epidemic hemorrhagic fever. (Oliver, J., and MacDowell, M., 1957, The renal lesion in epidemic hemorrhagic fever, J. Clin. Invest. *36*, 99.)

during the period of capillary leakage; the values remain depressed in the oliguric phase, then slowly return to normal.

PATHOLOGIC PICTURE

Characteristic lesions are found at autopsy in the pituitary, the right auricle and the kidney Hemorrhages, sometimes massive, occur in the first 2 organs mentioned The pale renal cortex stands out sharply beside the dark-red pyramids. Gelatinous edema occurs in the retroperitoneal tissues and mesentery in patients dying in the hypotensive phase but has disappeared in those who succumb during the late oliguric phase when pulmonary edema is frequently encountered The histologic changes in the kidney are discussed in detail below Other microscopic lesions, except those concerned with hemorrhages visible macroscopically, are meager and consist of scattered small focal areas of necrosis in the viscera. Bacterial pneumonia, when present, presents the ordinary histologic picture. Inflammatory lesions of the vascular tree are conspicuous by their absence, but intense capillary congestion is characteristic (Hullinghorst and Steer, 1953, Lukes, 1954)

The meticulous and beautiful studies of Oliver and MacDowell (1957) provide a correlation of the renal lesions of hemorrhagic fever with the clinical manifestations at different stages of the disease. Figure 56, which presents graphically the principal physiologic disturbances in this malady and indicates the accompanying renal vascular changes, is reproduced from their report

Histologic findings in the kidney in the late febrile and early hypotensive phases are described by these authors as follows. "There is a marked congestive hyperemia localized to the subcortical zone of the medulla, occurring not diffusely but in irregular patchy areas with no intertubular hemorrhage. There are some slight localized pressure effects of this congestion, both of compression and dilatation, on the tubules of nephrons that by chance pass through it, but no structural evidence of general cellular damage in any of the tubules The tubular passages are clear; there are few casts." Later in the hypotensive phase ". . . the evolution of the renal lesion . . . is evidenced by two phenomena; increase in intertubular congestion of the corticomedullary zone, and a swelling of the proximal convolutions The latter has the histologic appearance of an increased hydration of the protoplasm of the epithelial cells which reached the point of vacuolization" As the disease progresses, the vascular disturbances result in increasing damage to the tubules of the nephrons, thus the proximal convolutions in the congested subcortical areas are compressed though their lumens may be filled with hyaline material and desquamated epithelial cells With the beginning of the oliguric phase, true hemorrhages occur in the intensely congested areas. Tubules surrounded by such hemorrhages develop patchy necrosis of the entire wall, including the basement membrane. Furthermore, those portions of such affected tubules which lie in the cortex are dilated with coagulated protein material in their lumens. Such structural changes in a given nephron represent irreversible damage. In patients who recover, one assumes that either the process never reached the irreversible stage or a sufficient number of nephrons escaped anoxic necrosis. Persons dying during the diuretic phase show the usual renal reparative process of epithelial regeneration and replacement fibrosis; moreover, the general dilatation of cortical tubules is not present However, there is no restitution of structure (or function) in those nephrons whose continuity had been destroyed at any point.

Thus, the peculiar renal lesion of hemorrhagic fever is dependent on the same kinds of vascular changes which occur in many other parts of the body, but the response of the kidney is influenced by its unique anatomic structure Capillary dilatation and increased permeability which result from the infection are responsible for the periorbital flush and edema and the cutaneous hemorrhages, and also produce the proteinuria as well as the congestion, edema and hemorrhage in the medullary region With the development of hypotensive shock, hypoxia is intensified in the medullary areas already damaged, and necrosis of tubular portions of nephrons occurs.

EXPERIMENTAL INFECTION; HOST RANGE

Hemorrhagic fever of the type under discussion can be transmitted from man to man by blood, serum, or urine obtained during the first few days of illness Moreover, the infectious agent passes through a *Berkefeld* N filter (Smorodintsev, 1944; Smorodintsev et al., 1953; Kitano, 1944). Attempts by the

Russian and the Japanese investigators just mentioned to produce and maintain a recognizable disease in laboratory hosts with infectious materials were unsuccessful. Repetition of such attempts and extension of the studies to embrace most of the modern technics of virology failed to establish the agent in the laboratory despite the herculean efforts of American investigators of the Commission on Hemorrhagic Fever in Korea and of Russian workers in the Volga Basin (Chumakov, 1957)

ETIOLOGY

Since the transmissible agent of hemorrhagic fever has not been cultivated in laboratory hosts, little is known of the nature of this filterable microbe In studies employing volunteers, Smorodintsev (1944) found that the single convalescent human serum tested was capable of neutralizing the infectious agent No in vitro serologic procedure has been generally accepted as a useful diagnostic tool in this disease

DIAGNOSIS

In the absence of specific tests for the etiologic agent of epidemic hemorrhagic fever, the diagnosis is based on clinical and epidemiologic findings and in the fatal case is confirmed by the characteristic lesions Within the first several days after onset, the illness may be confused with leptospirosis, typhus fevers, idiopathic hemorrhagic purpura, hemorrhagic smallpox, or leukemia Stockard et al (1956) summarized the criteria for diagnosis of hemorrhagic fever as follows "(1) exposure in a known endemic area within 1 to 6 weeks of the onset of symptoms, (2) oral temperature over 100° F persisting for 4 or more days, (3) proteinuria of 0 5 gram per liter on 2 or more consecutive days, (4) hyposthenuria, specific gravity less than 1 024, during the second week of illness by 12-hour Fishberg concentration test or serial 24-hour urine specimens, and (5) one or more of the following petechiae, azotemia with blood urea nitrogen over 25 mg per 100 ml, oliguria with 24-hour urine output of less than 500 ml per day, diuresis with 24-hour urine output of at least 3,000 ml per day for 2 consecutive days, leukocytosis with white blood cell count exceeding 10,000 per μl, or hemoconcentration with hematocrit over 53 ml per 100 ml"

TREATMENT

No specific therapy is available The antibiotics and the drugs effective against bacterial, rickettsial and protozoal diseases are without value in this malady Furthermore, carefully controlled investigations of the Commission on Hemorrhagic Fever failed to reveal therapeutic benefit from convalescent serum Supportive treatment begins with early diagnosis and prompt transfer to a hospital staffed and equipped to cope with a disease characterized by such varied and extensive physiologic disturbances

EPIDEMIOLOGY

Hemorrhagic fever in Korea and the Far East occurs in rural areas throughout the year, but the incidence is greatest during two sharp seasonal peaks, one in the spring and the other in the fall Cases usually appear singly, but small outbreaks do develop, particularly when groups of susceptible persons are exposed in a hyperendemic area Careful study of such outbreaks among UN personnel in Korea has shown that (1) person-to-person infection is lacking, (2) food and water are unimportant in spreading the disease, and (3) all patients in a given outbreak acquire their infection within a day or so while exposed in a small piece of terrain, usually abandoned farmland (Gauld and Craig, 1954)

The American investigators noted the similarity in epidemiologic patterns of hemorrhagic fever and scrub typhus, which is transmitted by trombiculid mites Furthermore, they noted the correlation between the seasonal occurrence of such mites and the incidence of cases of hemorrhagic fever However, because of inability to handle the etiologic agent of hemorrhagic fever in the laboratory, they were unable to prove or disprove their hypothesis regarding trombiculids as vectors in a rodent-to-rodent cycle in nature or in transmission to man (Traub et al, 1954)

The early Japanese workers produced hemorrhagic fever in a volunteer by inoculating a pool of laelaptid mites from wild-caught Manchurian rodents (see Traub et al, 1954).

Chumakov (1957) obtained similar results with Gamasoidae mites collected in rodent burrows near homes of patients in the Yaroslavl region. He favored the hypothesis that human infection occurs from direct contact with excreta of infected rodents The consensus among the different groups of investigators is that wild rodents provide the reservoir of the agent and that mites serving as vectors maintain the infection chains in these hosts There is only indirect evidence regarding the mode of transmission to man

CONTROL MEASURES

In the absence of definitive knowledge about the way in which man contracts hemorrhagic fever, the control measures used by the UN Forces in Korea may be regarded as empirical. Nevertheless, the application of measures against mites and rodents, using the procedures described in Chapter 44, was followed by a sharp decrease in the case rate (Dews and Marshall, 1954)

There is no evidence of communicability of hemorrhagic fever from man to man Hence, isolation of patients and quarantine measures are not required

Rabies

(SYNONYMS Hydrophobia, *rage*, *Tollwut*, *Lyssa*, *rabbia*, *rabia*, *raiva*)

INTRODUCTION

Rabies is a type of encephalitis caused by a virus which exists in nature as a salivary gland infection of carnivorous animals The virus is transmitted from animal to animal and to man by biting All warm-blooded animals are susceptible The incubation period is from 1 to 3 months but may vary from 10 days to 8 months The mortality rate in man is nearly 100 per cent with canine rabies virus

The natural history indicates that the permanent hosts are found in the families *Mustelidae* and *Viverridae* Epidemics of rabies in domestic dogs, foxes, coyotes, jackals, wolves and skunks are the result of the development of large populations of such animals in regions where rabies is present as an inapparent infection in other animals Rabies in vampire bats and insectivorous bats appears to be a recently developed parasitism by the virus

Canine rabies is an example of aberrant parasitism where the natural capacity of the virus to produce encephalitis becomes the means by which it can adapt to the host, that is, by increasing the tendency of this host to bite In wild canines the disease is self-limited because this highly neurotropic virus eventually kills off the host until the chain of infection is broken

In vampire bats rabies virus may be maintained as an asymptomatic infection of the salivary glands. The virus from this host has a different spectrum of pathogenicity from that of canine rabies virus The capacity of rabies virus to invade the salivary glands, breast tissue and kidney tissue makes it possible for the virus to develop cycles of infection in some mammals not associated with encephalitis

HISTORY

Rabies has been known in Europe and Asia since ancient times The history of the disease has been primarily associated with the canine species Knowing that the dog is an aberrant host for the virus, this is a remarkable example of the persistence of basic genetic characters of a virus over a period of more than 2,000 years. Since antiquity the period of summer reckoned by the heliacal rising of the dog star, Sirius, has been referred to as "dog days" when dogs are supposed to be especially liable to spells of mad-

[illegible]

extremely vicious and aggressive without evident cause and, after a period of maniacal behavior, developed convulsive seizures and

paralysis, which were followed by death. Rabies in dogs and domestic animals was described by Democritus (500 B.C.) and Aristotle (322 B.C.). Celsus (A.D. 100) recognized the relationship of hydrophobia in man to rabies in animals and recommended cauterization of wounds produced by rabid dogs. Galen (A.D. 200) favored surgical resection of the wound area

Prior to the 18th century, rabies was known as a disease of wild canines, and domestic dogs played no significant part in its maintenance and spread. Rabies was known in western Europe as early as 1271, when it was prevalent among wolves in France. The first recorded epidemic among domestic dogs in urban centers occurred in Italy during 1708, by 1728 the disease had appeared in epidemic proportions in most of the major cities of Hungary, Germany and France. Rabies was known in England as early as 1613 but did not occur in epidemic proportions among dogs until 1734 Archives of the State of Virginia contain references to rabies in dogs as early as 1753, and those of North Carolina as early as 1762 Rabies was not recognized in South America until 1803 when it appeared among dogs in Peru, in 1806 an outbreak was observed among hunting dogs imported into La Plata, Argentina

The transmission of rabies from a rabid to a normal dog by inoculation of saliva was reported by Zinke in 1804 and by Gruner and by Salm-Reifferscheidt in 1813 These studies showed that the disease was infectious, and it was assumed that destruction of stray dogs and quarantine of other domestic dogs would eliminate the disease. Sanitary measures including these provisions were adopted in Norway, Sweden and Denmark, and by 1826 these countries were free from dog rabies. Although rabies was eliminated from some urban centers in continental Europe by dog-control regulations, these areas frequently became reinfected after a few years. For additional references concerning the early history of rabies, see the 2nd edition

Galtier, 1879, introduced domesticated rabbits as experimental animals for the diagnosis and the study of rabies, but the modern concept of this disease was developed by Pasteur and his associates. The first publication by this group of investigators relative to the etiology of rabies illustrates a problem which has repeatedly confused the study of virus diseases, i e , the isolation of a pathogen unrelated to the disease but transmissible in series in an experimental host. In this case, they isolated an organism from the saliva of a human being with rabies which produced hemorrhagic septicemia in rabbits. The subsequent discovery that the true infective agent of rabies could be recovered from the brain of an animal that died of the disease and the development of intracerebral inoculation by Roux opened the way for an extensive study of the disease (Pasteur et al, 1881). Since the infective agent obtained from brains of diseased animals could not be identified by microscopic examination and could not be cultivated in media used for the growth of bacteria, it was called virus, from the Latin word for poison The ultramicroscopic nature of the infective agent was postulated by Pasteur, but this was not established until Remlinger, 1903, showed that it would pass through Berkefeld filters impervious to bacteria

Pasteur et al (1884) were the first to modify the pathogenicity of a virus for a natural host by serial intracerebral passage in another species of host. In an attempt to develop a variety of rabies virus which could

an infection characterized by a short incubation period; such modified viruses were called fixed, to distinguish them from the natural, or so-called street, virus Though the virus maintained in rabbits at first appeared to become more virulent for dogs, it soon began to show a loss of pathogenicity, and, after 100 passages, the fixed virus had little capacity to infect dogs when given subcutaneously Pasteur had noted that cultures of the chicken-cholera organism, when stored for several weeks at room temperature, lost their pathogenicity but retained their immunizing capacity In an attempt to reproduce this phenomenon with rabies virus, he exposed the spinal cords of rabbits infected with fixed virus to drying at room temperature; then, by means of a series of 10 daily subcutaneous injections of fixed virus, graded from no infectivity to maximum infectivity as determined by intracerebral tests in rabbits, dogs were made resistant to experimental infection with the natural virus. This was a live virus vaccine. During 1885, a peasant boy, who had been severely bitten by a rabid dog, was taken to Pasteur, and, in view of the serious nature of the exposure and the plea that something be done, the boy was vaccinated in a manner similar to that used for immuni-

zation of dogs, the theory being that, if dogs could be immunized in a 2-week period so that they would resist infection with the natural virus, the long incubation period of rabies in human beings would allow the development of a high grade of immunity before the potential onset of the disease The treatment appeared to be without ill effects, and the boy remained well This became known, and other persons were taken to Pasteur for treatment, and the vaccine treatment for rabies soon was adopted as a routine procedure in medical centers throughout the world

Roux, 1887, introduced the use of glycerol as a preservative for maintaining the viability of virus in infected tissue This was applied to the production of vaccine by Calmette, 1891, whereby desiccated spinal cord tissue of varied infectivity could be kept at treatment centers by storage in glycerol Fermi, 1908, was the first to use chemical treatment of suspensions of fixed virus for the preparation of vaccine He introduced the use of phenol for this purpose, and Semple, 1919, by modification of Fermi's method, showed that phenol-treated vaccine could be rendered completely noninfectious and still retain its immunizing capacity, as determined by clinical trial in man

Negri (1903) described the occurrence of characteristic intracytoplasmic inclusion bodies in the nerve cells of human beings and animals proved to have been infected with rabies by isolation of the virus This discovery made possible a prompt microscopic diagnosis of most cases of animal rabies and has been used as a guide for human treatment Though intracerebral inoculation had been successfully employed for many years in the study of rabies in other species of laboratory animals, it was not adapted to the study of the disease in the white mouse until 1930 (Hoyt and Jungeblut, 1930) This animal has been found particularly useful for diagnostic work because of the short incubation period of the disease and the regular production of Negri bodies in its brain following intracerebral inoculation of street virus (Webster and Dawson, 1935)

The development of a method of vacuum desiccation of rabies virus from the frozen state by Harris and Shackell (1911) was a distinct advance Hodes et al (1940) were the leaders in the development of the ultraviolet light treatment of rabies virus for the preparation of a killed virus vaccine

Umeno and Doi (1921) introduced the use of a modified Fermi vaccine, containing active rabbit brain-fixed rabies virus, for the immunization of dogs Results obtained in the large-scale use of the vaccine in dogs in Japan showed that it was effective. A study by Johnson (1945b) on the duration of immunity in dogs vaccinated by the single injection method with a Semple type killed virus rabies vaccine provided the first definite evidence that dogs could be immunized for at least 1 year by this method The experimental method was new, i e, the challenge virus used was derived from the salivary glands of a dog that had died of rabies street virus, diluted and given by intramuscular inoculation so as to approximate natural exposure

Kligler and Bernkopf (1938) were the first to cultivate rabies virus in the developing chick embryo They showed that infection could be produced by inoculation of the chorio-allantoic-membrane and that the rabbit-fixed rabies virus used multiplied in this membrane as well as in the central nervous system of the embryo An avian brain-fixed variety of rabies virus (Flury strain) was developed by Johnson by intracerebral passage in 1-day-old chicks. The character present in the natural virus, which makes it possible for it to invade and multiply in the salivary glands, was eliminated by intracerebral passage for >100 generations in chicks This also reduced the capacity of the virus to invade the central nervous system of the mammalian host following peripheral inoculation The character which makes it possible for this virus to multiply in and destroy adult mammalian nervous tissue was markedly reduced, although not completely eliminated, by >180 serial yolk sac passages in chick embryos (Koprowski et al, 1954a) A single intramuscular injection of the low egg passage (LEP) Flury virus was found to produce a solid immunity to rabies, when tested in dogs by the method developed by Johnson (Koprowski, 1949).

The studies of rabies in vampire bats in Brazil by Queiroz-Lima (1934) revealed that this mammal can transmit rabies for several months as a symptomless carrier This was the first evidence that a mammal may serve as a host of rabies virus under conditions where the virus does not destroy the host In 1953 rabies virus was isolated from insectivorous bats killed in Florida (Venters et al, 1954), Pennsylvania (Witte, 1954) and Texas (Sullivan et al, 1954). This marked the beginning of the first known epidemic of rabies in insectivorous bats.

CLINICAL PICTURE

The onset of the disease is marked by 2 to 4 days of prodromal symptoms, such as fever, headache, malaise, anorexia, nausea and sore throat The temperature is elevated from 1° to 3° F and shows no marked fluctuation. Respiration tends to be shallow, and speech may be interrupted by sighing inspirations The early symptom of most diagnostic significance is some abnormal sensation about the site of infection This will occur in about 80 per cent of the cases and, when present, favors a diagnosis of rabies. The patient may complain of a dull, constant pain referable to the nervous pathways proximal to the location of the wound, or there may be intermittent stabbing pains radiating distally to the region of inoculation

In general, the early symptoms may be ascribed to the stimulative action of the virus affecting various groups of neurons, predominantly those of the sensory system. Though there is apt to be decreased sensitivity to local pain, such as that caused by the introduction of a needle, the patient may complain bitterly of drafts and bed clothes which produce a general stimulation of the skin There is apt to be sensitivity to other types of stimulation such as bright light and loud noise Objective signs include increased activity of muscle reflexes, muscle tics, and general increase in muscle tone Facial expression is apt to be overactive The pulse is rapid Symptoms referable to stimulation of the sympathetic nervous system include dilatation of the pupils, lacrimation, increased salivation and excessive perspiration

In some cases, the excitation phase is predominant up to the time of death However, depressive or paralytic symptoms may be predominant from the beginning or may supervene at any stage of the disease The onset of the excitement phase is gradual and is marked by increasing nervousness, insomnia, anxiety and apprehension There is a strong desire to be up, wandering aimlessly about. A sense of impending death is frequent Despite great fear and anxiety, a patient rarely bursts into tears

The outstanding clinical symptom of rabies is related to the act of swallowing, when fluid comes in contact with the fauces, it is expelled with considerable violence, and painful, spasmodic contractions of the muscles of deglutition and of the accessory muscles of respiration are produced Subsequently, the sight, the smell or the sound of liquids, by suggesting the act of swallowing, may precipitate spasm of the muscles of the throat The name "hydrophobia," or "fear of water," has been used to designate the disease since ancient times because of the frequent occurrence of this symptom in those developing the disease In some cases, the reflex irritability of the throat muscles is not so intense, and the patient exhibits no fear of water, though there may be difficulty in swallowing and a sense of constriction in the throat when the fluid or the food passes the fauces. In order to avoid the act of swallowing, a patient is apt to allow the saliva to drool from the mouth between attempts at expectoration Due to the difficulty in taking fluids by mouth, a patient is apt to develop progressive dehydration, so that the mouth and the tongue become dry and parched. As the disease progresses. the stimulation of the muscular system becomes more pronounced, and vermiform and fibrillar muscular contraction and general tremor may occur. Choking when attempting to swallow may result in such severe spasm of the respiratory muscles that prolonged apnea develops with cyanosis and gasping attempts at respiration. Convulsive seizures are common and may be so extreme as to produce opisthotonus Maniacal behavior, such as tearing clothes and bedding, is not uncommon, but vicious and murderous activity, such as biting and fighting, is rare, though it may occur. Periods of intense excitement are interspersed with those of relative quiet, at which time a patient is well oriented and answers questions intelligently

In the majority of cases a patient dies in the acute excitement phase of the disease during a convulsion Therefore, the paralytic phase caused by degeneration of motor neurons usually is not very evident. However, weakness of muscle groups related to the site of infection may be present early in the course of the disease Ocular palsies, leading to strabismus and in-co-ordination of ocular muscles, may occur. Weakness of the facial and the masseter muscles may be present, so that a patient has difficulty in closing the

eyes or the mouth, and the face becomes less expressive. Weakness of the muscles of phonation may be recognized by the development of hoarseness or loss of voice Examination of the eyes may show partial blindness of the central type, and, though the pupils may have been dilated and may have reacted poorly to light early in the disease, they at times become constricted or show inequality Hippus, nystagmus, diplopia, or strabismus may be noted Vertigo may be present, indicating middle ear disease, and, though this is apt to be an early symptom, it may develop at any period of the disease The corneal reflex is decreased or absent, and the corneae become dry The pulse rate may continue to be rapid with a rate of 100 to 120 at bed rest, but this may shift to bradycardia with a rate of 40 to 60 per minute. Cheyne-Stokes respiration is observed in most cases Though there may be stiffness of the neck, Kernig's and Brudzinski's signs are not elicited A positive Babinski reaction may be obtained Weakness of an extremity is preceded by loss of tendon reflexes Paralysis, when it develops, is of the flaccid type. Local sensation to pin prick, heat and cold is diminished, and in-co-ordination may be noted

If the acute excitement phase is survived, muscle spasms cease, and the patient becomes quiet The fear of water may disappear, if previously present, and the patient may be able to swallow, though with difficulty The face becomes expressionless, and anxiety and excitement are replaced progressively by apathy, stupor and coma In some cases there may be a period of a few hours during which it may seem that a patient is getting better, but this apparent remission is followed rapidly by progressive paralysis Depressive or paralytic symptoms may become predominant at any time during the course of the disease, and in some instances evidence of excitation of the nervous system may be absent Though a patient may complain of fever, headache, nausea and general discomfort at the beginning, the first significant sign is a sudden onset of weakness of one or more extremeties In rare instances, the course of the paralysis follows the pattern of Landry's syndrome and, beginning with the muscles of the legs, a progressive ascending paralysis develops with no relation to the site of the infection Patients developing the predominantly paralytic form of rabies seldom have difficulty in swallowing until the terminal phase of the disease The innervation of the musculature of the bladder and the intestinal tract is affected so that retention and obstipation develop early. Incontinence may develop, especially in patients with a prolonged illness There may be abnormal stimulation of the sex organs. Consciousness is retained until late in the course of the disease Rabies in man, as observed in Trinidad, British West Indies, following vampire bat bite, was uniformly of the paralytic type Nerve root pain preceded or accompanied the spreading paralysis in some cases
